

APPENDIX C₁
Chemical Data
Electronic Database

Documentation for Chemical Database

Database Structure

The Upper Arkansas River Basin Natural Resource Damage Assessment Chemical Database (the database) stores information concerning environmental conditions in the Upper Arkansas River Basin. One of the major goals of building the database is to compile large volumes of water, soil, and sediment quality information from numerous sources into a common repository, organized in a manner such that the combined data can be readily analyzed, (e.g. Statistical measures developed for specific time periods, and graphs of temporal and spatial trends produced). Another goal of the database is to provide a record of those data used in the site characterization.

The data are stored in the Microsoft Access 2000 relational database, and the database is structured in a manner that allows the information to be stored efficiently, while enforcing data integrity and minimizing redundancy. This is accomplished by storing the data in a set of hierarchically related tables that model the hierarchical nature of environmental data. The database contains information from numerous “datasets”. For the purposes of this report, a “dataset” is a single collection of data received as a discreet “deliverable”, e.g. data from a report, paper, spreadsheet, etc. Each dataset may contain data from numerous sampling stations. Many samples may be collected from an individual station over time. Each sample may be analyzed for numerous analytical parameters, and a numerical result will be generated to quantify each parameter. Thus, the primary tables in the database store information about data sources, stations, samples, analytical parameters, and analytical results. Logical connections, or links between data records in the various tables are maintained through table relationships and values in key data fields. All key values used in relationships between the primary data tables are long integer data type, and are assigned during the data import process by the import program.

Many data fields in the primary data tables store information as coded values. These codes are typically integer values or one or two –character text strings. Each data field that stores coded values is linked to a lookup table that defines the codes. The use of data codes and lookup tables promotes data storage efficiency and data consistency. Data codes are assigned during the import process, and a database table documents these assignments and translates the original values to the data codes.

All relationships in the database are set up and maintained to enforce referential integrity. This means that entries in a coded value field are limited to the values in that field’s associated lookup table, and that a sample record (for example) cannot exist in the samples table without an associated record describing the sampling station in the stations table.

Tables, queries, and other database objects are named following standard naming conventions. Object names consist of a lower-case prefix to indicate object type, followed by a proper case descriptive name. The prefixes tbl, lk, and qry are used to indicate primary data tables, lookup tables, and queries, respectively.

A table of Data Sources for the Upper Arkansas Site Characterization Database can be found at the end of this appendix. An Entity-Relationship Diagram for the database table is also included in this appendix.

Dataset Processing & Import

Raw datasets received from all data sources were checked for a minimum set of required information for each sample, and if sufficient information was available to allow processing, a restructuring process was performed prior to importing into the database. Datasets were prioritized for entry into the database based on how recent and how complete and pertinent the data were for site characterization purposes. A pair of digital data folders was created to store files associated with each dataset. A read-only folder was created to preserve the original unprocessed data files as they were received from the data provider. The second folder was made to store files as they underwent the restructuring necessary for import to the database.

Datasets were required to have (at a minimum) a) complete sample location, i.e. known geographic coordinates, b) sample collection date, c) analytical parameter, d) numerical result value, and e) units of measure information in order to be included in the database. In addition to these minimum requirements, every effort was made to obtain sample depth, analytical method, and limits of detection data for each dataset.

Sampling station location data was requested, and typically received, as X-Y coordinate pairs. In cases of datasets lacking coordinate data but having detailed location descriptions, the descriptions and GIS software were used to generate coordinates. Datasets lacking both coordinates and detailed location descriptions were not usable. However, in cases where a small percentage of a dataset's stations lacked sufficient locational data these stations were included in the database in the hope that the locational data may be obtained through ongoing data acquisition efforts. (Data associated with these stations were excluded from data analysis efforts until coordinates were obtained.)

Sample collection date information was requested and typically received as complete month/day/year dates. Certain datasets contained incomplete sample date information, typically as month/year. The database structure requires dates to be stored in month/day/year format. When incomplete dates were encountered, a request was made to the data provider to obtain the missing information. If attempts to obtain exact sample date data were unsuccessful, sample dates were assumed based on available information and a note was made in the samples table for those records.

After all essential data components were obtained, the datasets were prepared for import to the database. All data was brought into the database through a custom import program. This program is built into the database, and receives the incoming data via an import template table. The process of adding data to the database involves two principal steps. First, each dataset must be processed into the structural format of the template table, and then the import program is run to move the data elements from the template table to the appropriate tables in the repository database.

A Microsoft Access 2000 database file was created for each source dataset for pre-processing purposes. Each one of these database files contains all original data files and tables associated with a dataset and any queries, utility programs, and intermediate tables that were created in order to restructure the dataset into the import table. The import table is a flat-file table containing 34 data fields to accommodate anticipated data elements, five long text fields for notes and miscellaneous data, and three long integer fields to store key values assigned by the import program.

At the conclusion of the pre-processing, each dataset (in the import template format) was brought into the main repository database and the import program was run. This program consists of four steps initiated from a user interface form. Step one opens a form for entry of general information about the dataset including: title, author, source organization, date published, etc. The second step runs a procedure that converts all null values in the import table to missing data flags. This is necessary because procedures used in the program require that all data fields contain non-null values. Null date and time data elements were set to 11/11/1111, and null numeric and text values were replaced with -9999.99. Step three of the program opens an interactive form used to assign lookup values for data fields that are stored as coded values tied to lookup tables. The form displays a list of fields for which lookup values need to be assigned. When a field is selected, two new lists are populated. One displays a list of unique values for the field from the import table, and the other lists the values currently in the associated lookup table. Lookup codes are assigned by selecting a value from the import table list and double-clicking the desired value in the lookup table list. An option exists on the form to add entries to the lookup table if necessary. All lookup code assignments are written to a database table. This table is used by the final step of the import program to translate the original values to lookup codes as records are written to the

repository database tables. The table also provides documentation of the data translations made during import. The final step of the import process runs a series of procedures that assign key values used in the database relationships, and append the data to the appropriate tables in the repository database.

Post-Import Data Conversion

The database was constructed with the philosophy of preserving data values as they were originally reported, to the extent possible. This approach minimizes opportunity for errors induced by data conversion and manipulation, and facilitates easy comparison between the database and original files, but is in apparent conflict with the database goal of normalizing data to a readily comparable state. This conflict was handled by storing original data values in the database, but then providing means to dynamically normalize the data to a readily comparable state. This normalization process was carried out for station locations, station types, analyte names, numerical values/units of measure, and data qualifiers.

Sampling stations provided numerous data normalization challenges. Due to the variety of data sources, numerous station naming conventions and coordinate systems were encountered. Station names were not usable in efforts to group all samples collected at a given location because different data sources assigned different names to common sampling stations. Conversely, common station names were assigned to a variety of different sampling locations by various organizations. In addition, stations associated with sample records common to multiple datasets were often found to have slightly different coordinates in the separate datasets. These discrepancies were introduced by the variety of conventions and electronic storage formats used by various data source organizations. The GIS was used to project all coordinates into a standard geographic projection (UTM, NAD 27 meters). Coordinate data are stored in the stations table both in their original form and in the standard projection. The standard projection was used for all mapping and analysis tasks. Stations were normalized for data grouping and comparison in the GIS using spatial buffers. For station counting purposes, all stations within two meters of each other were considered to be the same station and assigned a common buffer identifier. These identifiers are of long integer data type and were written to a field in the stations table by a GIS macro. For duplicate data identification across multiple datasets, a 100-meter buffer was also generated for each station. These buffer identifiers were used to identify stations for all data analysis tasks.

Station type information is used by data queries to group and select data. For example, a query may use station type as a selection criterion to retrieve all data associated with river sampling stations. Some source datasets contained a data field indicating sampling location type, such as river, soil boring, well, seep, etc. This data was translated to lookup codes during the import process and stored in the stations table and station type lookup table. With other datasets the station type may not be explicitly

stated in the source files, but may be readily inferred from text describing the station, sample media reported, or station X-Y location. For example, stations associated with groundwater samples were inferred to be wells. A location type table in the database stores sampling location type information for all stations. The table contains a record corresponding to every station record in the stations table. Location type codes are assigned in this table for each station after a dataset is imported. A code source field indicates whether the location type code was based on data in the original source file, or inferred based on other information such as station description or X-Y location.

Each station in the database was assigned a summary zone, or reach designation, in order to group data by spatial location within the drainage basin. Summary zones exist for distinct reaches of the Arkansas River, as well as its major tributaries and surrounding upland areas. Stations in a dataset were assigned to summary zones after the dataset was imported. Summary zone assignments were based primarily on station location, but other data such as textual descriptions of sampling locations were used to support zone assignments. This auxiliary data was given greater weight when station coordinates were of questionable quality.

Analytical result values are stored in the results table in the units of measure reported in the original data files. Records in the results table are linked to records in the parameters table. The parameters table stores the original parameter names and units as reported by the data provider. In order to readily query and compare values from different data sources a system of standard analyte names and units is necessary. For example, a source dataset may report values for ‘Dissolved Zinc’ in micrograms per liter. Another source dataset may report values for ‘Zn, D’ in milligrams per liter. To facilitate comparison of this data, the parameters table contains Standard Analyte, Standard Unit, and Multiplier data fields used to normalize data to common names and units. Records for the example given would be assigned a Standard Analyte of ‘Zinc, Dissolved’ and a Standard Unit of ‘mg/L’. Records having original units of milligrams per liter would be given ‘1’ as a multiplier, while records originally reported as micrograms per liter would be assigned a multiplier of ‘0.001’. The standard analyte and unit fields, when used in conjunction with the product of the original value and the multiplier, produce a normalized dataset. This approach is used by all saved queries that extract results information for comparison and analysis. A similar approach is used with sample depth data. Values are stored in their original units, and a standard unit and multiplier are used to normalize values.

Many datasets contained a variety of qualifiers associated with result values. During dataset pre-processing and import these qualifiers were put into one of three data fields depending on whether they were assigned by an analytical lab, data validator, or other or unknown source. After data were imported to the database each record was assigned an additional qualifier code. This code serves as a master

qualifier and groups all other qualifiers into several basic categories for data comparison and analysis purposes. Records were classified as either unqualified, non-detect, or rejected.

Analysis Sub-Datasets

Additional data processing steps were performed to prepare the data for use in a data analysis program. These steps include setting flags to indicate duplicate records (records with the same location, date, parameter, and analytical result, arising from obtaining partially overlapping datasets from multiple agencies or sources), statistical outliers, and assigning codes to indicate the appropriate analysis time period and flow regime (high flow, low flow) for each record. This additional processing and all subsequent data analysis were performed in a separate database file. This was done to keep file sizes manageable and to keep a clear distinction between raw data and the processed data used for statistical analysis and interpretations. The database is a raw data repository that preserves data as it was received from the data provider to the extent possible. The data analysis database file accesses the tables in the raw data repository through live links, and uses queries to create static copies of the appropriate data for charting and statistics purposes. It is in these copied tables that all interpretive flags and codes are assigned. A set of queries and Visual Basic programs in the data analysis file are used to refresh the analysis tables as needed. The refresh process deletes the current analysis table, queries the data repository and constructs a new analysis table containing the appropriate data, then runs a series of procedures that update the several “flag” fields in the table.

Analysis tables are created for each of the following media: Surface Water, Groundwater, Sediment, Lowland Soil, and Upland Soil. The queries that create these tables limit the data to include only complete and valid records for the media and parameters of interest. Records lacking coordinates are excluded, as are those describing field duplicate and lab QA/QC samples. Records flagged as rejected or otherwise invalid by the data validator are also excluded. The queries that create the analysis tables normalize all parameters to standardized parameter names, and convert numerical values to consistent units of measure so that they may be readily compared.

Duplicate Flags

The database is a compilation of numerous source datasets from numerous data providers. Many of these datasets originate from databases maintained by public agencies or from consultants working with these public datasets. Thus, there can be considerable overlap between datasets received from different data providers. Datasets were added to the database in their entirety, no effort was made to exclude records that were already included in the database from a previously added data source. This was

done to preserve datasets intact and avoid difficulties in identifying areas of overlap induced by rounding and other formatting performed by individual dataset providers. As a preferred alternative to identifying and excluding duplicated records prior to import, a Visual Basic program was developed to identify duplicated records during the analysis table refresh process.

Each analysis table contains a field that stores a duplicate flag for each record. This flag's value is initialized to '0' for all records at the start of the duplicate flagging program. Then the program creates a temporary table containing all unique combinations of normalized sample location, date, analyte, and value entries from the subject table. The program steps through the records in this temporary table. For each record in the temporary table the program retrieves all records from the subject table matching the record's normalized sample location, date, analyte, and value. If only one matching record is retrieved, the record's duplicate flag is left as 0 and the program moves on to the next record in the temporary table. If more than one matching record is retrieved, the program steps through the matching records and increments their duplicate flags from 1 to n (the number of duplicates). When the program has finished running, a duplicate-free recordset may be retrieved by selecting only records having a duplicate flag of 0 or 1.

Time Flags

For data analysis purposes, the time continuum is split into three periods corresponding to historical events influencing water flow and quality. The annual cycle is also split into periods of high and low flow. The dates of these period breaks are stored in a table in the analysis database (illustrated below). Each analysis data table contains data fields that store a period value and flow flag for each record. A series of procedures are run to update the period and flow flags based on each record's sample date when an analysis data table is refreshed.

Period Name	Start	End
High Flow	5/1/XX	8/14/XX
Low Flow	8/15/XX	4/30/XX
Period 1	1/1/1900	5/31/81
Period 2	6/1/81	1/31/92
Period 3	2/1/92	Present Date

Non-Detects

Records in the analysis tables having qualifiers indicating non-detect results were updated to one-half of the reported value (the reported value for non-detect records is typically the detection limit). This operation is performed by a Visual Basic procedure when the analysis tables are refreshed.

Outlier Flags

Outlier flagging is performed on the surface water data analysis table. Data records which are determined to be statistical outliers are flagged with an ‘O’ in the qualifier field. The outlier flagging procedure begins by resetting all qualifiers in the surface water data analysis table to the qualifier value stored in the main data repository (clears all outlier flags). The program then retrieves lists of the summary zone groups and analytes to be considered in the outlier test. Currently the program considers data from Arkansas River reaches 0-4 (grouped collectively as Ark R) and the Cal Gulch and Cal Gulch at Ark Riv zones (grouped together as Cal Gulch). Analytes considered include dissolved and total Cadmium, Copper, Lead, and Zinc, as well as Hardness. The program steps through all possible zone-analyte combinations. For each iteration, the procedure retrieves a recordset consisting of all data records for the current zone and analyte. It then calculates the mean and standard deviation of this recordset. The procedure then finds all records within the recordset having values greater than or equal to the mean plus four standard deviations (one-sided test), and updates the qualifier field to ‘O’ for these records. (It should be noted that data from all dates and flow periods are considered together in the outlier tests. The recordsets used in the outlier tests are defined solely by summary zone and analyte.)

Table Value Standards

Acute and chronic Colorado Table Value Standards (TVS) were calculated for dissolved cadmium, copper, lead, and zinc for selected river reaches. These calculations were performed by a Visual Basic program and the resulting values were stored in a table in the analysis database file. The program begins by creating lists of all analytes, river reaches, time periods, and flow periods for which standards are to be calculated. It then steps through all possible combinations of analyte, reach, time period, and flow period. During each iteration of the loop, the program calculates an average hardness value for use in the standards calculations, then calculates the acute and chronic standards based on the average hardness, and counts the number of records exceeding each of the standards for the current analyte-reach-time-flow scenario.

Average hardness values are calculated for each scenario using available hardness data applicable to the scenario's reach, time period, and flow period. Hardness, Total Hardness, and Calculated Hardness values were used, while Carbonate and Non-Carbonate Hardness values were not included. For TVS calculation purposes, average hardness values less than 25 mg/L or greater than 400 mg/L were reset to 25 and 400 mg/L, respectively.

Charting and Statistics

The data analysis database file includes a set of forms that provide a graphical user interface for selecting and charting data. This interface provides users with a means to select specific data subsets based on sample media, river reach, analyte, flow period, and time period criteria, and display charts and statistical summaries of the selected data. Two types of charts are available in the program. One is a time-series chart displaying a parameter's values for a single reach over time. The other allows comparison between reaches by displaying a parameter's minimum, maximum, and average values for multiple reaches.

A maximum series-axis value is specified in the database for each parameter that is plotted on the time-series charts. These values are used by the charting program to limit the scale of the vertical axis so that all charts produced for a given parameter have the same scale and are readily comparable. Data points that exceed the chart limit are displayed in a table below the chart.

There are several display options for the time-series charts that may be toggled on and off using check boxes on the user interface. Data points representing non-detect analysis results may be displayed with a different symbol than results greater than the detection limit. Acute and chronic Table Value Standards may be displayed on the chart as horizontal lines at the standard levels. This option is available when the 'High Flow' and/or 'Low Flow' options are selected, but is disabled when the 'All Flow' option is chosen because Table Value Standards only exist for the high and low flow divisions of the annual flow cycle. An option is available to display period breaks on the chart when the 'All Periods' sample date option is chosen. Period breaks appear on the charts as vertical lines marking the division points between the three data analysis periods.
