SUMMARY: A ground-based survey has been used since 1985 to estimate the number of nests and eggs of geese and eiders on the Yukon-Kuskokwim Delta (YKD), Alaska. 2008 was a year of fair to good production for geese and eiders. Depredation and nest abandonment rates were moderate for most species. Recent 10-year trends in nests populations are stable for all waterfowl except for spectacled and common eiders and white-fronted geese that are continuing to grow significantly. We estimated that spectacled eiders built 4,991 nests and laid 19,321 viable eggs on the YKD coastal zone in 2008. The estimate of spectacled eider nests was 8% above the 1985-2007 average. This year marked the first time in the history of the survey that the recent 10-year average growth rate for spectacled eiders is significantly above 1.00 (alpha > 0.90). Spring arrived later on the YKD in 2008 compared to recent years, but a long-term advance in hatch dates is apparent over the course of this survey.

INTRODUCTION:

Annual assessment of nest population size and egg production of geese and eiders on the Yukon-Kuskokwim Delta (YKD) provides information for the Spectacled and Steller's Eider Recovery Team, the Pacific Flyway Technical Committee, participants in cooperative goose management plans, and biologists interested in waterfowl status and trends in western Alaska. A ground-based sampling procedure has been used since 1985 to estimate the number of nests and eggs for spectacled eiders (*Somateria fischeri*), cackling geese (*Branta hutchinsii minima*), emperor geese (*Chen canagica*), greater white-fronted geese (*Anser albifrons frontalis*), and other nesting waterbirds on the YKD. The ground-based nest survey provides an estimate of nest population size and potential production. The ground survey is conducted concurrently with an aerial breeding pair survey (Bollinger and Eldridge 2008, Platte and Stehn 2008) that provides an index to population size. Together, these surveys contribute long-term data needed to understand goose and eider population status and reproductive success.

Tim Moser

Tim Moser

Starting in 2006 we improved analysis methods by incorporating nest detection rates (Bowman and Stehn *manuscipt in prep.*), reducing sampling error in expansion factors, and restricting analyses of historical data to plots within the current survey area. These changes resulted in population estimates that differ from those reported in previous annual reports (Fischer et al. 2007).

METHODS:

We used a ground-based sampling procedure to monitor goose and eider nest populations and potential production on the YKD coastal zone from 1985 to 2008 (Fig. 1). Boundaries of the survey area included all lands on the Yukon Delta National Wildlife Refuge (YDNWR) containing medium and high nest densities of spectacled eiders (based on aerial and ground observations 1985-1993, USFWS unpubl. data). We excluded privately owned high density nesting habitat near Kokechik Bay, two patches on south Nelson Island, and several tracts near Hazen Bay because annual access could not be assured. From 1994-1997 and 2000-2008, plots were selected within 716 km^2 (core spectacled eider habitat; hereafter "core"), which comprised 5.6% of the total coastal zone. In 1998, 1999, and prior to 1994, plots were selected within a slightly a larger portion of the coastal zone. In this report, estimates of nest population size and egg production are based on plots within the core

Julian Fischer

716 km^2, whereas estimates of clutch size and hatch date use data from plots within and beyond the core area.

We used GIS and custom-written TrueBASIC computer programs to randomly select 85 plots within the core 716 km^2 ground sampled area in 2008 (Fig. 1). Areas sampled during the preceding five years were excluded from the random selection process. We transferred plot boundaries to digital color infrared aerial photographs (1:15,000 or 1:10,000) and IKONOS satellite imagery for field use. We included plots regardless of juxtaposition to lakes and rivers. Plot size was 402 m by 805 m (0.32 km^2) in 1988-1994 and 1997-2008. Plot sizes were variable in 1985-1987 (0.16-1.66 km^2), 0.45 km^2 in 1995, and 0.36 km^2 in 1996.

Plots were searched by 2-4 biologists who were transported either by Cessna 185 float-equipped aircraft or by motorboat. Two boat crews originated from the YDNWR Kanaryamiut Field Station and worked plots accessible from the Aphrewn and Opagyarak rivers. A third boat crew was transported directly from Bethel to plots on the Naskonat Peninsula, directly north of Kigigak Island. Biologists at Kigigak Island (YDNWR), Big Slough (USGS), Manokinak River (USGS), and Tutakoke River (University of Nevada, Reno) searched plots near their camps. All sites dry enough for a nest were examined for active and destroyed waterfowl, crane, loon, and gull nests. Incidental nesting records of other species were recorded as encountered (data available upon request), but most shorebird and passerine nests were likely missed.

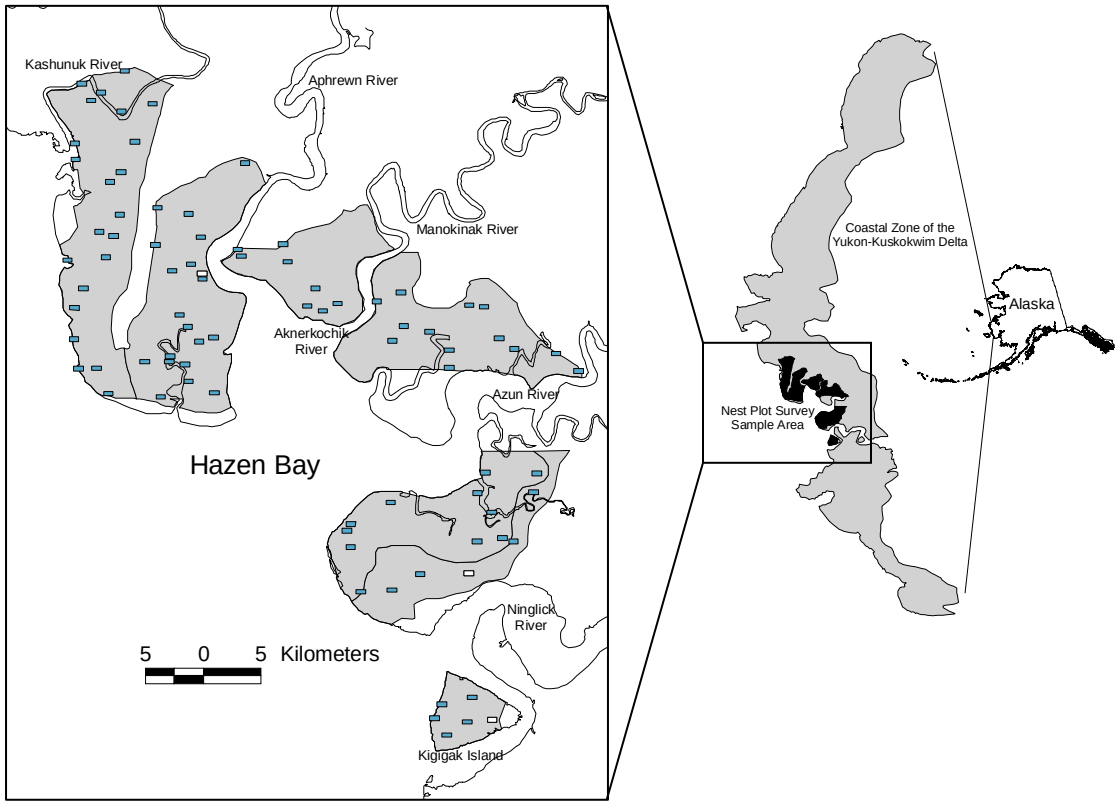

Figure 1. Location of 85 randomly selected plots within the ground sampled area (716 km^2) relative to the Yukon-Kuskokwim Delta coastal zone (12,832 km^2), Alaska, 2008. Sampled plots are represented by solid rectangles. Three additional plots were selected but not sampled in 2008.

At each nest we recorded species, nest status, nest site, and stage of incubation. Species was determined by visual confirmation of an adult at the nest or by comparing down and contour feathers in the nest bowl with a photographic field guide (Bowman 2008). We determined stage of incubation for all species by measuring float angles of eggs from active nests (Westerskov 1950). Hatch dates were estimated from incubation stage of eggs found on plots. Hatch date estimates prior to 1985 were derived from plots established by Butler (1983).

Red-throated (*Gavia stellata*) and Pacific loons (*Gavia pacifica*) rarely remain near their nest sites when disturbed by plot searchers, and their nests are essentially indistinguishable from each other (Bowman 2008), so we applied the ratio of aerial observations of each loon species, as recorded from an aerial platform (Platte and Stehn 2008) to determine the relative numbers of loon nests for each species. To reduce variation in the ratio of loon species caused by sampling error in aerial indices, we used a localized 7-year average (from the current year, 3 prior years, and 3 following years, as available) of the annual ratio of loon species For example, the localized 7-year average ratio for 1995 was the mean of ratios from 1992-1998; whereas for 2008 we use the mean of ratios from years 2005 to present.

Julian Fischer

The mean and variance of the number of nests and eggs per plot was based on a simple random sample of plots. The estimates of nests and eggs were expanded to the ground sampled area (716 km^2) based on the size and number of plots for each year. Nest population estimates were corrected for detection rate using a model that considers species, nest activity status, observer experience, and nest site location (Bowman and Stehn *manuscript in prep.*).

The corrected estimates for nests and eggs in the ground sampled area were expanded to the entire coastal zone of the YKD based on a stratified analysis of an aerial survey of the entire YKD coastal zone (12,832 km^2; Butler et al. 1988, Bollinger and Eldridge 2008, Platte and Stehn 2008). To expand the ground-based estimates, we annually calculated the ratio of the aerial breeding population index outside the ground-sampled area ("OUT") to the aerial index within the ground-sampled area ("IN"). We used the localized 7-year average (from the current year, 3 prior years, and 3 following years, as available) of 1+ Out/In ratio as an expansion factor for a given year. Variance estimates of nest populations expanded to the entire coastal zone incorporate the variance of the Out/In ratio. The aerial breeding population index for most species was based on twice the number of singles plus the number of birds in pairs observed, because single geese, cranes, and ducks observed are assumed to be the mates of unobserved females on nests. Flocks of these species were not included in the aerial index, except with brant. For swans, the number of single birds observed was not doubled. For loons and gulls, the total number of birds observed was used as the index. The expansion of estimated nests and eggs from the ground sampled area to the entire coastal zone is based the assumption that observed breeding bird indices obtained from aerial surveys provide an accurate linear relationship with the number of nests within versus outside of the ground sampled area.

Data were tabulated, edited, sorted and analyzed using Excel, and nest population, hatch date and clutch size estimates were calculated using customized TrueBASIC programs.

The estimated total number of nests is a direct measure of effective breeding population size and an index to the size of the population of adults that are potential nesters. The estimated total number of eggs is a measure of the number of young that could potentially augment the fall population if they survive through summer. The proportion of nests that are active when the plots are searched is an index to nest success; the actual proportion of nests that produced young is lower because some nests are lost after plots are searched. The relative production rate measures how the number of eggs per total nests constructed in a given year compares to the long-term average for each species; thereby quantifying the relative annual contribution of eggs to the population on a per pair basis.

Julian Fischer

RESULTS:

We searched 82 plots from 1 June to 18 June (Fig. 1). Crews based at the Kanaryamiut Field Station searched 35 plots, boat-based crews searched 33 plots, a Yukon Delta NWR crew at Kigigak Island searched three plots, a USGS crew at Big Slough searched four plots, a USGS crew at the Manokinak River searched four plots, and a University of Nevada, Reno crew at Tutakoke River searched three plots. Three of the 85 randomly selected plots were not sampled due to access and weather delays that prevented completion of field work prior to onset of hatch. Crews located 3,694 nests within plot boundaries in 2008 comprised of 1,579 cackling goose, 355 emperor goose, 600 greater white-fronted goose, 108 spectacled eider, and 1,052 nests of other species. Calculations of clutch size and hatch date also included an additional 43 nests located outside of plot boundaries. We present nest population, egg production, and nest success estimates in figures with accompanying tabulated data for each species (Fig. 2). Estimated hatch date for each species is presented in Table 1. The following section presents general descriptive results for each species.

<u>Cackling Geese (*Branta hutchinsii minima*)</u>

Julian Fischer

Production of cackling geese was fair in 2008. Total numbers of nests were down from 2007 (Fig. 2) but remained above the long-term (1985-2007) and short-term (1998-2007) averages. Egg production in 2008 was higher than the long-term average; however, owing to relatively low clutch size and nest success, the overall egg production was down from 2007 and below the short-term mean. As a result, the relative production rate of eggs per total nest (i.e. number of breeding pairs) was below average. Following thirteen years of positive

growth, the growth rate of cackling goose nests and eggs has been essentially flat during the last decade. The estimates of number of nests and eggs were fifth and sixth highest, respectively, since 1985. Average hatch date for cacklers in 2008 was three days later than 2007 and two days earlier than the previous long-term average (1985-2007; Table 1).

Emperor Geese (*Chen canagica*)

Potential production of emperor geese was good in 2008. Total numbers of nests and eggs were down from 2007 (Fig. 2) but remained above the long-term (1985-2007) and short-term (1998-2007) averages. Nest success and clutch size were similar to short and long-term means, and resulted in a relative production rate just below the long-term mean. Nest and egg population size have been variable over the course of this survey and have resulted in non-significant growth rates in both short- and long-term time spans. Similar to other waterfowl species, estimated hatch date for emperors in 2008 was two days later than 2007 and one day earlier than the previous long-term average (1985-2007; Table 1).

Greater White-fronted Geese (*Anser albifrons frontalis*)

Potential production of white-fronted geese was poor to fair in 2008. Total numbers of nests and eggs were down from 2007 (Fig. 2) but remained above the long-term (1985-2007) and short-term (1998-2007) averages. In contrast, egg production in 2008 was down sharply from the previous four years (Fig. 2) resulting in lower than average production in the short term (1998-2007). Clutch size and nest success were both lower than short and long-term averages. As a result, the relative production rate in 2008 was below average, and the third lowest value in 24 years. White-front nest and egg population growth rates have been high throughout the duration of the survey but have slowed somewhat during the last decade. Similar to other waterfowl species, estimated hatch date for white-fronts in 2008 was three days later than 2007 and one day earlier than the previous long-term average (1985-2007; Table 1).

Black Brant (*Branta bernicla nigricans*)

The nest plot survey was not designed to monitor colonial nesting birds such as black brant, and we purposely excluded most primary colonies from the sample area. Kigigak Island supports one of the primary brant colonies on the YKD and is included in the ground sampled area. Five primary brant colonies are monitored annually by digital photographic surveys (see Wilson 2008). The nest plot survey does provide an estimate of nests populations from non-colonial brant, small satellite colonies, and one of the five major YKD colonies (Kigigak Island). In these areas, potential production of brant in

2008 was fair to good. The number of nests in 2008 was down from the previous year. Nest population estimates were slightly below the long-term average, and slightly above the short-term average. Clutch size in 2008 was higher than the short-term mean, but lower than the long-term mean, whereas nest success was higher than short and long-term averages. As a result, the relative production rate in 2008 was very close to average. Nest and egg population sizes have been variable over the course of this survey and resulted in non-significant growth rates in both short- and long-term time spans. Similar to other waterfowl species, estimated hatch date for brant in 2008 was two days later than 2007 and one day earlier than the previous long-term average (1985-2007; Table 1).

Tundra Swans (*Cygnus columbianus*)

Potential production of tundra swans was fair in 2008. Total numbers of nests and eggs were down from 2007 (Fig. 2) and were below short- (1998-2007) and long-term (1985-2007) averages. Clutch size was also down from 2007 and below short- and long-term averages. Nest success in 2008, was unchanged from the short-term average but down from the long-term mean. As a result, the relative production rate in 2008 was below average. For tundra swans, nest and egg population sizes have been variable over the course of this survey and resulted in non-significant growth rates in the short-term. Over the long-term, however, both nest and egg population sizes have increased significantly. Unlike other waterfowl species, estimated hatch date for tundra swans in 2008 was later than 2007 by three days, and one day later than the previous long-term average (1985-2007; Table 1).

Sandhill Cranes (*Grus canadensis*)

Potential production of sandhill cranes was good in 2008. Total numbers of nests and eggs were down from 2007 (Fig. 2) and were below the short- (1998-2007) and long-term (1985-2007) averages. Similarly, clutch size in 2008 was below short and long-term means. Despite these declines, nest success of those cranes that bred was higher than short- and long-term averages resulting in an average relative production rate. Nest and egg population sizes have been variable over the course of this survey and have resulted in non-significant growth rates in both short- and long-term time spans. Unlike the waterfowl species, estimated hatch date for sandhill cranes in 2008 was over a week later than 2007 and one day later than the previous long-term average (1985-2007; Table 1).

Spectacled Eiders (*Somateria fischeri*)

Potential production of spectacled eiders was good in 2008. Total numbers of nests and eggs were up from 2007 (Fig. 2) and remained above the short-term (1998-2007) and long-term (1985-2007) averages. Clutch size in 2008 was higher than short- and long-term means. However, nest success was down sharply from 2007 and was below short- and long-term averages. Together, these measures resulted in

an average relative production rate. Estimated numbers of nests have grown since the early 1990s, and this change is reflected in a significant positive short-term growth rate (1999-2008). In contrast, the long-term growth rate (1985-2008) is negative, largely due to the high estimates measured in the mid and late 1980s. Annual estimates of egg production are variable due to fluctuations in breeding conditions and have led to non significant trends in short- and long-term time periods. Estimated hatch date for spectacled eiders in 2008 was the same as in 2007 and two days earlier than the previous long-term average (1985-2007; Table 1).

Common Eiders (*Somateria mollissima*)

Potential production of common eiders was good in 2008. Total numbers of nests and eggs were down sharply from 2007 (Fig. 2) but remained above the short-term (1998-2007) and long-term (1985-2007) averages. Clutch size in 2008 was very similar to short- and long-term means. Nest success was down from 2007 but remained above the short- and long-term average. Together, these measures resulted in an average relative production rate. Nest numbers and egg production have grown throughout the course of this survey. This change is reflected in significant positive short- (1999-2008) and long-term (1985-2008) growth rates. Similar to other waterfowl species, estimated hatch date for common eiders in 2008 was four days later than 2007 and two day earlier than the previous long-term average (1985-2007; Table 1).

Tim Moser

Loons

Potential production of Pacific loons (*Gavia pacifica*) and red-throated loons (*Gavia stellata*) was fair in 2008. Estimates of nests and eggs for both species were close to estimates in 2007 and remained above the short- and long-term averages. While nest success for both species in 2008 was similar to short- and long-term means, clutch sizes were down sharply, resulting in a lower than average relative production rate. Nest and egg population sizes have been variable over the course of this survey and resulted in non-significant growth rates in both short- and long-term time spans. Similar to waterfowl species, estimated hatch date for both loon species in 2008 was four days later than 2007 and two days earlier than the previous long-term average (1985-2007; Table 1).

Gulls and Terns

Julian Fischer

Colonial nesting species such as gulls (glaucous gulls [*Larus hyperboreus*], Sabine's gulls [*Xema sabini*], mew gulls [*Larus canus*]), and arctic terns [*Sterna paradisaea*]) are not monitored with precision by the nest plot survey. Nonetheless, the survey does provide a measure of potential production for these species. In 2008, potential production was good for gulls and terns (Fig. 2). Numbers of nests and eggs in 2008 was down from the previous year for all but mew gulls, but estimates were higher than the

short- and long-term averages. Clutch size for all three gull species was close to short- and long-term averages**.** Nest success for most gulls was higher than short- and long-term averages. The exception was mew gulls whose nest success was relatively low. In contrast, terns had lower than average clutch size and higher than average nest success in 2008. Trends in nest populations of gulls and terns are highly variable over the course of the survey; however, positive growth in the nest populations of mew gulls is apparent during the most recent decade. Estimated hatch date of gulls and terns in 2008 was up to five days later than 2007 and up to four days earlier than the long-term average (Table 1).

DISCUSSION:

The nest plot survey was designed to provide annual estimates of nest population size and trend, and predict potential production (active eggs) and hatching dates for nesting geese (cackling geese, emperor geese, greater white-fronted geese) and eiders (spectacled and common) on the Yukon-Kuskokwim Delta coastal zone.

In general, production in 2008 was fair for cackling and white-fronted geese, and good for emperor geese and eiders. We observed low nest success for cackling and white-fronted geese and spectacled eiders, but overall numbers of nests with eggs helped offset low success. Among the principal species monitored in the survey, only common eiders exhibited relatively high nest success. The relative production rate (contribution of eggs per bird relative to the long-term average) was below the median for all species except glaucous gulls. For white-fronted geese, 2008 represented the third lowest relative production rate during the 24 years of data collection.

Incidence of nest desertion and depredation was variable among plots and not isolated to one region within the ground sampled area. Rather, nest failure was distributed throughout the study area, and plots with severe nest loss were juxtaposed with plots with high nest success. Arctic fox (*Alopex lagopus*) have been identified as important nest depredators on the coastal zone, particularly in brant colonies (Anthony et al. 1991). While fox were likely contributors to egg loss on study plots in 2008, there is no indication that fox presence necessarily resulted in high levels of depredation in all instances. For example, waterfowl nest success on plots with fox sign (fur, tracks, active dens, fox observed) ranged from 50% to 100%. Further, mean nest success was virtually the same among plots with and without sign of fox presence (84% and 86% success, respectively). Most primary brant colonies were excluded from the study area; thus we do not have data to measure the degree of fox predation within those colonies.

Spring was cold and relatively late in 2008. The Kuskokwim River broke up at Bethel on May 13, ten days later than 2007 and two days later than the previous 26-year average (NOAA 2008). Timing of waterfowl nest initiation is closely correlated with spring breakup (Raveling 1978, Dau and Mickelson 1979). Consequently, in 2008 waterfowl nests hatched approximately four days later than the previous year and two days earlier than the long-term averages. A significant trend in earlier waterfowl nest initiation is apparent over the 27-year history of this study (Fig. 3). Based on nesting data since 1982, we estimate that on average, hatch for cackling geese for which the most data are available, occurs 0.4 days earlier each year. This change translates to an advance of over 10 days during the 1982-2008 time period.

In general, goose nest population trends parallel trends derived from aerial breeding pair surveys (Bollinger and Eldridge 2008, Platte and Stehn 2008). Estimates of cackling goose nests were at record lows in the mid-1980s prior to adoption of the

cooperative Yukon-Kuskokwim Delta Goose Management Plan that provided much needed protection for nesting and wintering populations of geese (Pamplin 1986). Data from this nest plot survey and aerial breeding pair surveys (Bollinger and Eldridge 2008, Platte and Stehn 2008) show that by the late-1980s, the cackling goose population of nests and pairs increased rapidly, peaking in the late-1990s. Since 1999, trends for cackling geese have been relatively flat (this study, Bollinger and Eldridge 2008). Unlike the other goose species, populations of emperor geese did not increased markedly after adoption of the Yukon Delta Goose Management Plan, although a slow annual increase in the long-term trends from ground and air surveys is apparent (this study, Bollinger and Eldridge 2008). The population of greater white-fronted geese has increased dramatically on the coastal zone of the YKD since the mid-1980s and has continued to grow at moderate levels in recent years (this study, Bollinger and Eldridge 2008).

Tim Moser

The number of spectacled eider nests has varied widely since the beginning of the survey in the mid-1980s. The average long-term growth rate (1985-2008) is negative, but the rate is not significantly different from 1.00. However, for the first time in the history of this study, the recent 10-year growth rate is significantly above 1.00 (alpha > 0.90).

Aerial surveys of spectacled eider pairs on the YKD show a similar contemporary increasing trend as the nest population size trend (Platte and Stehn 2008). The aerial survey indices are influenced by survey timing, and an analysis of aerial data from 1993-2006 that corrected for survey timing reported a growth rate of 1.042 (Stehn et al. 2006), a rate nearly identical to the nest population trend from the most recent 10 years.

Spectacled eider nest success is variable among years and generally reflects varying levels of nest predation. Plots are visited one time, so the measure of nest success is an overestimation of actual success because some nests undoubtedly fail after the plot is searched. Nonetheless, the pattern in nest success measured from the nest plot survey (number of active nests divided by total nests times 100%, corrected for detection rate) generally matches nest success at Kigigak Island (successful hatched nests/total nests) where nests are visited every seven days until hatch (Lake 2008). In 2008, the nest plot survey and intensive surveys at Kigigak both reported relatively low nest success (Fig. 4). The largest difference between these measures of nest success from these two surveys was noted in 2001 and 2003, years of very poor production, where perhaps many nest failures occurred late in nesting. Alternatively, a localized factor may have caused low success on Kigigak Island during those years. Large annual fluctuations in production estimates are reduced when sampling occurs over a large portion of the nesting range, such as in the nest plot survey described here.

A comparison of estimates from the photographic colony survey and the ground plot survey suggests that many brant occur as dispersed nesters or in satellite colonies outside most primary colonies (Fig. 5). Photographic methods were initiated in the 1990s to monitor the nest population of brant in major colonies with greater precision than ground surveys or standard straight line aerial waterfowl surveys (Wilson 2008). Estimates of brant nests derived from ground plot and photographic surveys both indicate a slow decline in nest populations over the last 17 years (Fig. 5).

The population sizes of goose and eider nests should not be interpreted as direct estimates of population size. For example, a year of poor nesting conditions may result in fewer nesting attempts (and thus nests), but does not represent a loss of adults from the breeding population. Instead, the lower number of nests and eggs in a poor nesting year will likely contribute to a reduction in total population size in future years via lower recruitment. This nest survey does not provide precise annual estimates for species that occur in low densities, such as loons, cranes, and swans, or those with clumped distributions, such as brant, common eiders, and gulls. However, long-term averages should be accurate.

A primary advantage of the random nest plot sampling procedure over intensive local studies is that it assures applicability of estimates to the entire coastal zone not just the immediate areas around intensive biological study camps. Moreover, the single brief visit to scattered plots ensures that the monitoring of populations occurs with minimum disturbance. The expansion of estimated nests and eggs from the ground sampled area to the entire coastal zone is based the assumption that observed breeding bird indices obtained from aerial surveys provide an accurate linear relationship with the number of nests within versus outside of the ground sampled area. By using a 7-year localized average Out/In ratio, the variation in aerial estimates due to sampling error is moderated.

Annual changes in nest population size are less informative than long-term trends because of sampling error, changes in observers, distribution of plots, and small sample size for less common species. Only several years of consistent declines or increases are likely to indicate a true change in the number of nests and eggs produced on the Yukon-Kuskokwim coastal zone. We believe that a graphical presentation (Fig. 2) enables better interpretation of data than analysis of year-to-year changes in population size. Large annual changes in nest population size probably reflect sampling error or result from extremes in nesting effort and success, rather than real population change.

ACKNOWLEDGMENTS

The nest plot survey is a cooperative project between Region 7 Migratory Bird Management (MBM) and the Yukon Delta National Wildlife Refuge (YDNWR). Special thanks go to Thomas Doolittle (YDNWR) and Doug Staller (Kenai NWR, formerly with YDNWR) for financial support and logistical coordination. We also thank Victor Anvil (YDNWR) for maintenance of essential facilities and equipment used by the nest plot crews. We are indebted to Hollis Twitchell (YDNWR), Robert Sundown (YDNWR), and Chuck Moore (Regional Aviation Management- RAM) for safe and superb flying during the course of the survey; and special thanks go to George Walters (YDNWR) whose aviation skills, project support, and good cheer have contributed significantly to the success of this project for many years. We also thank Bryce Lake (YDNWR), Louie Andrew (YDNWR), Jim Sedinger (University of Nevada, Reno- UNR), Amanda Walker (UNR), Joel Schmutz (USGS), Patrick Lemons (USGS), Margaret Petersen (USGS), and Matt Sexson (USGS) for providing personnel during their already busy field seasons. We also thank Paul Anderson (MBM) for air support of personnel and supplies, and Bill Eldridge (MBM), Karen Bollinger (MBM), and Bob Platte (MBM) for aerial survey data. Bob Platte also provided invaluable GIS data processing, plot delineation, and preparation of photomaps. We thank Bill Larned, Tim Bowman, and Bob Platte for critical reviews of this report. The following individuals collected data in 2008: Stan Afcan, Doug Alcorn, Mike Blom, Chris Dau, Lynn Denlinger, Tasha DiMarzio, Tyrone Donnelly, Julian Fischer, Paul Flint, Barbara Heindl, Bryce Lake, Susan Lawrence, David Leal, Patrick Lemons, Jessica Lewis, Sarah Lovivond, Dennis Marks, Sarah McCloskey, David Messmer, Tim Moser, Russ Oates, Steve Olson, Bill Ostrand, Anthony Pagano, Molly Schreiner, Rob Scuckard, Matt Sexson, Terry Sharpe, Lynn Snoddy, Matt Sorum, Heather Wilson, and Tamara Zeller.

Figure 2 (Subsequent pages). Population size (± 90% CI) and trends of waterbird nests and egg production on the Yukon-Kuskokwim Delta Alaska, 1985-2008, with accompanying tabulated data. Column heading definitions follow:

Year = survey year;
N plots = number of ground sampled plots used in the analysis;
Sampled km^2 = total area searched (N plots*plot size);
Nest index IN = number of nests within the core 716 km^2 ground sampled area uncorrected for nest detection;
SE nest index IN= standard error for nest index;
Avg nest detection rates = annual proportion of nests detected based on predictive model (considers species, nest status, habitat, observer experience, Bowman and Stehn *manuscript in prep*);
Corrected nest IN = Nest index corrected for nest detection;
7 yr avg aerial Out:In ratio = the seven-year localized average ratio of aerial observations seen out of the ground sampled area vs. in the ground sampled area (seven years are based on from the current year, 3 prior years, and 3 following years data as available);
Corrected nests OUT = number of nests extrapolated beyond the ground sampled area based on the 7-yr localized average Out:In ratio, corrected for nest detection rate;
Total nests In+Out = total number of nests in the YKD coastal zone, corrected for nest detection rate;
SE total nests = standard error for total nest estimate;
Total eggs In+Out = total number of viable eggs at time of plot search in the YKD coastal zone, corrected for detection rate;
SE total eggs = standard error for total egg estimate;
Total eggs/active nests = total viable eggs In+Out divided by the nests with eggs In+Out, corrected for detection rate;
Total eggs/total nests = total viable eggs In+Out divided by the total nests In+Out, corrected for detection rate;
Corrected % nest success = number of active nests divided by total nests times 100%, corrected for detection rate;
Relative production rate = Total eggs/total nests divided by the long-term average of total eggs/total nests. This measure describes how the production of eggs per nests compares to the long-term average illustrating the relative contribution of eggs to the population on a per breeding pair basis.

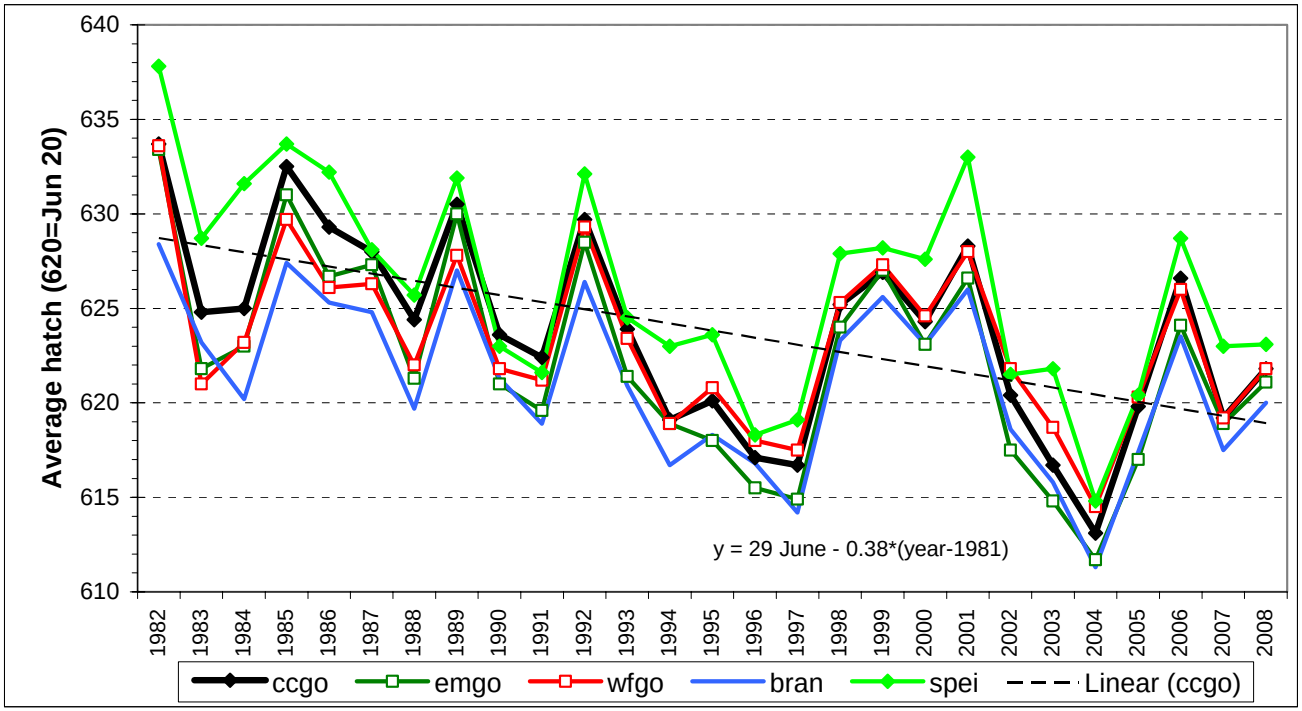

Figure 3. Estimated average hatch date based on egg float angles, 1982-2008. Linear regression on cackling goose hatch date indicates an average advance of 0.4 days per year.

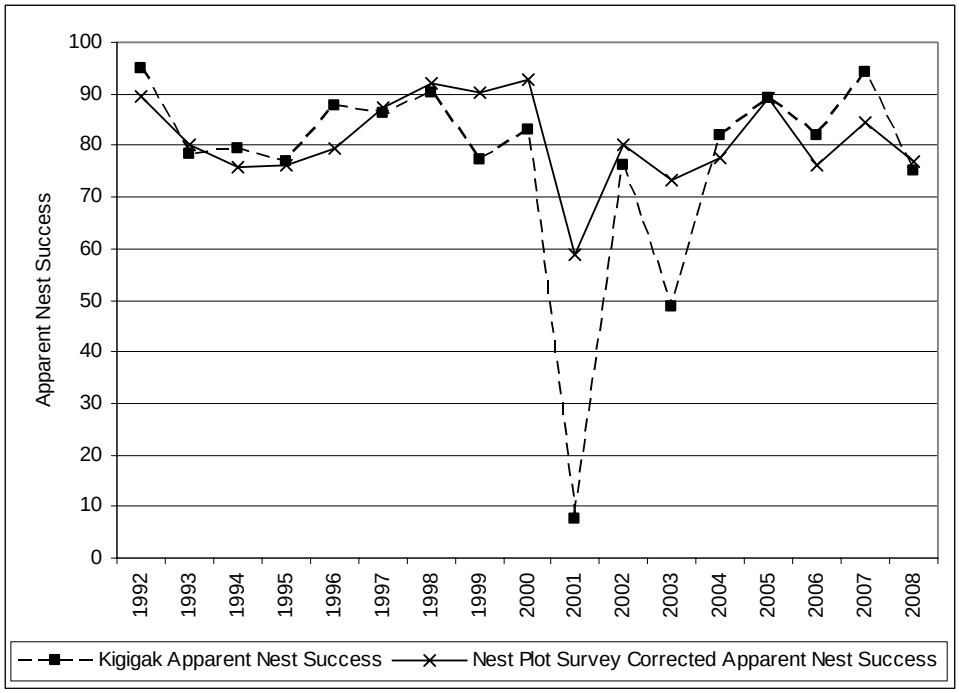

Figure 4. Comparison of spectacled eider apparent nest success measures at Kigigak Island (successful hatched nests/total nests; Lake 2008) and the Yukon-Kuskokwim Delta nest plot survey (active nests at time of search/total nests, corrected for nest detection rate), 1992-2008.

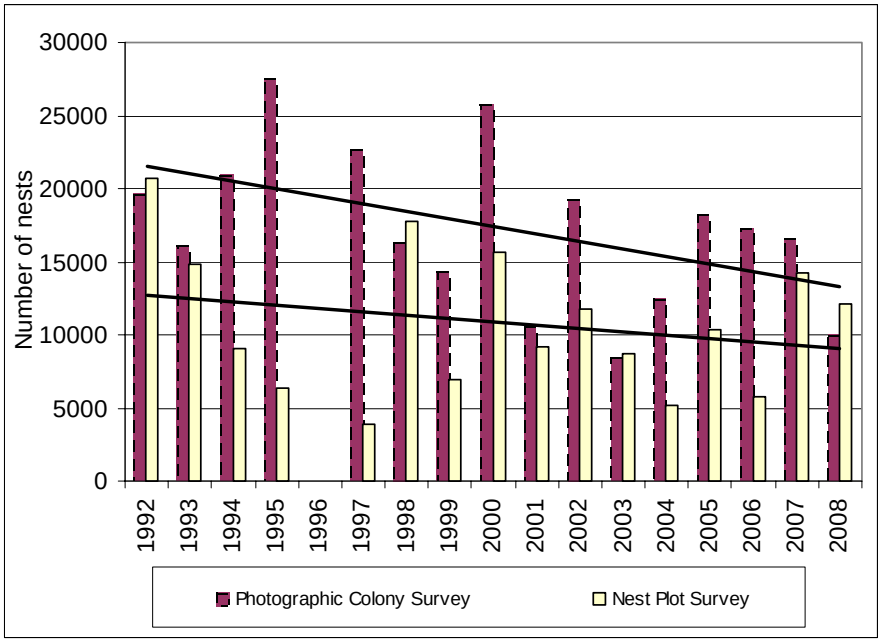

Figure 5. Numbers of black brant nests as measured by an aerial photographic survey in 5 primary colonies (Wilson 2008) and as measured by this survey in the ground sampled area (nest estimates in ground sampled area only, not expanded to entire coastal zone). The aerial photographic survey and ground survey both include the colony at Kigigak Island.

Table 1. Estimated hatch date based on egg float angles. Means calculated using nest as sample unit. Years with fewer than 3 nests per species not included in calculations.
