Leatherbacks are champion deep divers among sea turtles with a maximum recorded dive of over 4,000 m (Eckert et al. 1989; López-Mendilaharsu et al. 2009). Dives are typically 50 to 84 m and 75 to 90 percent of time duration is above 80 m (Standora et al. 1984). Leatherbacks off South Africa were found to spend <1 percent of their dive time at depths greater than 200 m (Hays et al. 2009). Dive durations are impressive, topping 86 min, but routinely 1 to 14 min (Eckert et al. 1989; Eckert et al. 1996; Harvey et al. 2006; López-Mendilaharsu et al. 2009). Most of this time is spent traveling to and from maximum depths (Eckert et al. 1989). Dives are continual, with only short stays at the surface (Eckert et al. 1989; Eckert et al. 1986; Southwood et al. 1999). Off Playa Grande, Costa Rica, adult females spent 57–68 percent of their time underwater, diving to a mean depth of 19 m for 7.4 min (Southwood et al. 1999). Off St. Croix, adult females dove to a mean depth of 61.6 m for an average of 9.9 min, and spent an average of 4.9 min at the surface (Eckert et al. 1989). During shallow dives in the South China Sea, dives averaged 6.9 to 14.5 min, with a maximum of 42 min (Eckert et al. 1996). Off central California, leatherbacks dove to 20 to 30 m with a maximum of 92 m (Harvey et al. 2006). This corresponded to the vertical distribution if their prey (Harvey et al. 2006). Leatherback prey in the Gulf of Alaska are frequently concentrated in the deep-scattering layer (Hodge and Wing 2000). Mean dive and surface durations were 2.9 and 2.2 min, respectively (Harvey et al. 2006). In a study comparing diving patterns during foraging versus travelling, leatherbacks dove shallower (mean of 53.6 m) and moved more slowly (17.2 km/day) while in foraging areas while travelling to or from these areas (81.8 m and 51.0 km/day) (Fossette et al. 2009b).

4.2.8.9 Vocalization and Hearing

Sea turtles are low-frequency hearing specialists, typically hearing frequencies from 30 to 2,000 Hz, with a range of maximum sensitivity between 100 and 800 Hz (Bartol et al. 1999c; Lenhardt 1994b; Lenhardt 2002; Moein Bartol and Ketten 2006; Ridgway et al. 1969). Piniak et al. (2012) found leatherback hatchlings capable of hearing underwater sounds at frequencies of 50 to 1,200 Hz (maximum sensitivity at 100 to 400 Hz). Hearing below 80 Hz is less sensitive but still possible (Lenhardt 1994b).

These hearing sensitivities are similar to those reported for two terrestrial species: pond and wood turtles. Pond turtles respond best to sounds between 200 and 700 Hz, with slow declines below 100 Hz and rapid declines above 700 Hz, and almost no sensitivity above 3 kHz (Wever and Vernon 1956). Wood turtles are sensitive up to about 500 Hz, followed by a rapid decline above 1 kHz and almost no responses beyond 3 or 4 kHz (Patterson 1966).

4.2.8.10 Status and Trends

Leatherback sea turtles received protection on June 2, 1970 (35 FR 8491) under the Endangered Species Conservation Act and, since 1973, have been listed as endangered under the ESA, but declines in nesting have continued worldwide. Consideration of the status of populations outside of the Action Area is important under the present analysis to determine the risk to the affected population(s) bears on the status of the species as a whole. Breeding females were initially estimated at 29,000 to 40,000, but were later refined to approximately 115,000 (Pritchard 1971b; Pritchard 1982). Spotila et al. (1996) estimated 34,500 females, but later issued an update of 35,860 (Spotila 2004a). The species as a whole is declining and local populations are in danger of extinction (NMFS 2001a; NMFS 2001b).

Reliable estimates of survival or mortality at different life history stages are not easily obtained. The annual survival rate for leatherbacks that nested at Playa Grande, Costa Rica, was estimated to be 0.654 for 1993 and 1994 and 0.65 for those that nested in 1994 and 1995 (Spotila et al. 2000). Rivalan et al. (2005) estimated the mean annual survival rate of adult leatherbacks in French Guiana to be 0.91. Pilcher and Chaloupka (2013) used capture-mark-recapture data for 178 nesting leatherbacks tagged at Lababia beach, Kamiali, on the Huon Coast of Papua New Guinea over a 10-year austral summer nesting period (2000-2009). Annual survival probability (ca. 0.85) was constant over the 10-year period. Annual survival was lower than those estimated for Atlantic rookeries (Dutton et al. 2005; Rivalan et al. 2005). For the St. Croix, U.S. Virgin Islands population, the annual survival rate was approximately 0.893 (confidence interval = 0.87 to 0.92) for adult female leatherbacks at St. Croix (Dutton et al. 2005). Annual juvenile survival rate for St. Croix was estimated to be approximately 0.63, and the total survival rate from hatchling to first year of reproduction for a female hatchling was estimated to be between 0.004 and 0.02, given assumed age at first reproduction between 9 and 13 (Eguchi *et al*. 2006). In Florida, annual survival for nesting females was estimated to be 0.956 (Stewart 2007). Spotila et al. (1996) estimated the first year (from hatching) of survival for the global population to be 0.0625.

Heavy declines have occurred at all major Pacific basin rookeries, as well as Mexico, Costa Rica, Malaysia, India, Sri Lanka, Thailand, Trinidad, Tobago, and Papua New Guinea. This includes a nesting decline of 23 percent between 1984 to 1996 at Mexiquillo, Michoacán, Mexico (Sarti et al. 1996). According to reports from the late 1970s and early 1980s, three beaches on the Pacific coast of Mexico supported as many as half of all leatherback turtle nests for the eastern Pacific. Leatherback sea turtles appear to be in a critical state of decline in the North Pacific Ocean. The leatherback population that nests along the Pacific Ocean was estimated to be over 91,000 adults in 1980 (Spotila et al. 1996) or greater than 39,000 nests (NMFS USFWS 2013), but is now estimated to number 3,172 total nests (NMFS USFWS 2013). Leatherback turtles have experienced major declines at all major Pacific basin rookeries. Since the early 1980s, the eastern Pacific Mexican population of adult female leatherback turtles has declined to slightly more than 200 individuals during 1998 to 1999 and 1999 to 2000 (Sarti et al. 2000). Spotila et al. (2000) reported the decline of the leatherback turtle population at Playa Grande, Costa Rica, which had been the fourth largest nesting colony in the world. Between 1988 and 1999, the nesting colony declined from 1,367 to 117 female leatherback turtles. Based on their models, Spotila et al. (2000) estimated that the colony could fall to less than 50 females by 2003 to 2004. Fewer than 1,000 females nested on the Pacific coast of Mexico from 1995 to 1996 and fewer than 700 females are estimated for Central America (Spotila et al. 2000). The number of leatherback

turtles nesting in Las Baulas National Park declined rapidly during the 1990s, from about 1,500 females during the 1988 to 1989 nesting season, to about 800 in 1990 to 1991 and 1991 to 1992 to 193 in 1993 to 1994 (Williams et al. 1996) and 117 in 1998 to 1999 (Spotila et al. 2000). Spotila (2004b) reported that between 59 and 435 leatherbacks nest at Las Baulas each year depending on the El Niño–La Niña cycle.

There are 28 known nesting sites for the western Pacific Ocean stock, with 5,000 to 9,100 leatherback nests laid annually across the western tropical Pacific Ocean, from Australia and Melanesia (Papua New Guinea, Solomon Islands, Fiji, and Vanuatu) to Indonesia, Thailand, and China (Chaloupka et al. 2004a; Dutton 2006; Hirth et al. 1993; Hitipeuw et al. 2007; Suarez et al. 2000). The largest extant leatherback nesting assemblage in the Indo-Pacific lies on the northern Vogelkop coast of Irian Jaya (West Papua), Indonesia, with roughly 3,000 nests recorded annually (Dutton et al. 2007; Putrawidjaja 2000; Suárez et al. 2000). The Western Pacific leatherback metapopulation harbors the last remaining nesting aggregation of significant size in the Pacific with approximately 2700 to 4500 breeding females (Dutton et al. 2007; Hitipeuw et al. 2007). The total number of nests per year for the Jamursba-Medi leatherback nesting population ranged between a high of 6,373 nests in 1996 and a low of 1,537 nests in 2010 (Hitipeuw et al. 2007) and 1,596 in 2011 (Tapilatu et al. 2013). Nesting at Terengganu, Malaysia is 1 percent of that in 1950s (Chan and Liew 1996b). The South China Sea and East Pacific nesting colonies have undergone catastrophic collapse. Overall, Pacific populations have declined from an estimated 81,000 individuals to < 3,000 total adults and subadults (Spotila et al. 2000). The number of nesting leatherbacks has declined by an estimated 95 percent over the past 20 years in the Pacific (Gilman 2009). Drastic overharvesting of eggs and mortality from fishing activities is likely responsible for this tremendous decline (Eckert 1997; Sarti et al. 1996). The most recent overall estimate for Papua Barat, Indonesia, Papua New Guinea, and Solomon Islands is 5,000 to 10,000 nests per year (Nel 2012).

Of the three sea turtle species that have been sighted around Guam and the CNMI during marine surveys, the leatherback turtle is the least common (DON 2003b). This species is occasionally encountered in the deep, pelagic waters of the Marianas archipelago, although only a few occurrence records exist (Eckert et al. 1999). Recent National Oceanic and Atmospheric satellite tracking of leatherback turtles indicates sea turtles departing from regional nesting habitats and transiting through MITT waters (Benson et al. 2007a; Benson et al. 2011a). As for nearshore waters, Eldredge (2003)noted a rescue in 1978 of a 249 lb (112.9 kg) leatherback from waters southeast of Cocos Island, Guam. From 1987 to 1989, divers reported seeing leatherbacks in the waters off Harmon Point, Rota; however, none have been seen in the area in recent times (DoN 2010c). Leatherbacks do not nest at any of the islands in Micronesia. As a result, the occurrence of leatherback turtles would be considered rare throughout the year in nearshore waters of the Action Area. Since leatherback occurrences in the waters off Guam and the CNMI would most likely involve individuals in transit, occurrence is not expected in coastal (i.e., shelf) waters around any of the islands in the Action Area. The Navy's NMSDD estimates 0.00022 leatherback sea turtles per km^2 in the MITT Action Area (DoN 2014).

4.2.8.11 Natural Threats

Sea turtles face predation primarily by sharks and to a lesser extent by killer whales (Pitman and Dutton 2004). Hatchlings are preyed upon by herons, gulls, dogfish, and sharks. Leatherback hatching success is particularly sensitive to nesting site selection, as nests that are overwashed

have significantly lower hatching success and leatherbacks nest closer to the high-tide line than other sea turtle species (Caut et al. 2009a). The fungal pathogens *Fusarium falciforme* and *F. keratoplasticum* an kill in excess of 90 percent of sea turtle embryos they infect and may constitute a major threat to nesting productivity under some conditions (Sarmiento-Ramırez et al. 2014). Lost timber on beaches and beachcast logs acan trap adult females nesting on Gabon beaches, resulting in mortality (Ikaran 2013).

4.2.8.12 Anthropogenic Threats

Leatherback nesting and marine environments are facing increasing impacts through widespread development and tourism along nesting beaches (Hamann et al. 2006; Hernandez et al. 2007; Maison 2006; Santidrián Tomillo et al. 2007). Structural impacts to beaches include building and piling construction, beach armoring and renourishment, and sand extraction (Bouchard et al. 1998; Lutcavage et al. 1997). In some areas, timber and marine debris accumulation as well as sand mining reduce available nesting habitat (Bourgeois et al. 2009; Chacón Chaverri 1999; Formia et al. 2003; Laurance et al. 2008). Lights on or adjacent to nesting beaches alter nesting adult behavior and is often fatal to emerging hatchlings as they are drawn to light sources and away from the sea (Bourgeois et al. 2009; Cowan et al. 2002; Deem et al. 2007; Witherington 1992; Witherington and Bjorndal 1991b). Leatherbacks are much more likely to emerge and not nest on developed beaches and much more likely to emerge and nest on undeveloped stretches (Roe et al. 2013). Plastic ingestion is very common in leatherbacks and can block gastrointestinal tracts leading to death (Mrosovsky et al. 2009). Along the coast of Peru, 13 percent of 140 leatherback carcasses were found to contain plastic bags and film (Fritts 1982). A leatherback found stranded along the northern Adriatic had been weakened by plastic ingestion, likely leading to an infection that ultimately killed the individual (Poppi et al. 2012). Although global warming may expand foraging habitats into higher latitude waters, increasing temperatures may increase feminization of nests (Hawkes et al. 2007b; James et al. 2006; McMahon and Hays 2006b; Mrosovsky et al. 1984). Rising sea levels may also inundate nests on some beaches. Egg collection is widespread and attributed to catastrophic declines, such as in Malaysia. Harvest of females along nesting beaches is of concern worldwide.

Bycatch, particularly by longline fisheries, is a major source of mortality for leatherback sea turtles (Crognale et al. 2008; Fossette et al. 2009a; Gless et al. 2008; Petersen et al. 2009). Wallace et al. (2010) estimated that between 1990 and 2008, at least 85,000 sea turtles were captured as bycatch in fisheries worldwide. This estimate is likely at least two orders of magnitude low, resulting in a likely bycatch of nearly half a million sea turtles annually (Wallace et al. 2010c); many of these turtles are expected to be leatherbacks.

Spotila (2000) concluded that a conservative estimate of annual leatherback fishery-related mortality (from longlines, trawls and gillnets) in the Pacific Ocean during the 1990s is 1,500 animals. He estimates that this represented about a 23 percent mortality rate (or 33 percent if most mortality was focused on the East Pacific population). In the Pacific Ocean, between 1,000 and 1,300 leatherback sea turtles are estimated to have been captured and killed in longline fisheries in 2000 (Lewison et al. 2004). Shallow-set longline fisheries based out of Hawaii are estimated to have captured and killed several hundred leatherback sea turtles before they were closed in 2001. When they were re-opened in 2004, with substantial modifications to protect sea turtles, these fisheries were estimated to have captured and killed about 1 or 2 leatherback sea

turtles each year. Between 2004 and 2008, shallow-set fisheries based out of Hawaii are estimated to have captured about 19 leatherback sea turtles, killing about 5 of these sea turtles.

Donoso and Dutton (2010) found that 284 leatherbacks were bycaught between 2001 and 2005 as part of the Chilean longline fishery, with two individuals observed dead; leatherbacks were the most frequently bycaught sea turtle species. Between 8 and 17 leatherback turtles likely died annually between 1990 and 2000 in interactions with the California/Oregon drift gillnet fishery; 500 leatherback turtles are estimated to die annually in Chilean and Peruvian fisheries; 200 leatherback turtles are estimated to die in direct harvests in Indonesia; and, before 1992, the North Pacific driftnet fisheries for squid, tuna, and billfish captured an estimated 1,000 leatherback turtles each year, killing about 111 of them each year. Currently, the U.S. tuna and swordfish longline fisheries managed under the Highly Migratory Species Fishery Management Plan (HMS FMP) are estimated to capture 1,764 leatherbacks (no more than 252 mortalities) for each 3-year period starting in 2007 (NMFS 2004). In 2010, there were 26 observed interactions between leatherback sea turtles and longline gear used in the HMS fishery (Garrison and Stokes 2011). All leatherbacks were released alive, with all gear removed for the majority of captures. While 2010 total estimates are not yet available, in 2009, 285.8 (95 percent CI: 209.6 to 389.7) leatherback sea turtles are estimated to have been taken in the longline fisheries managed under the HMS FMP based on the observed takes (Garrison and Stokes 2010). Lewison et al. (2004) estimated that 30,000 to 60,000 leatherbacks were taken in all Atlantic longline fisheries in 2000 (including the U.S. Atlantic tuna and swordfish longline fisheries, as well as others). Use of circle versus traditional J hooks can severely curtail bycatch (Santos et al. 2012) and new regulations are being developed and implemented in several countries around the world for their use. Finkbeiner et al. (2011) estimated that annual bycatch interactions total 1,400 individuals annually for U.S. Atlantic fisheries (resulting in roughly 40 mortalities) and one hundred interactions in U.S. Pacific fisheries (resulting in about ten mortalities). Garrison and Stokes estimated 597 interactions between leatherbacks and the U.S. Atlantic longline fishery in 2012, mostly with hooks embedded (Garrison and Stokes 2013). Mortality of leatherbacks in the U.S. shrimp fishery is now estimated at 54 turtles per year. Data collected by the NEFSC Fisheries Observer Program from 1994 through 1998 (excluding 1997) indicate that a total of 37 leatherbacks were incidentally captured (16 lethally) in drift gillnets set in offshore waters from Maine to Florida during this period. Observer coverage for this period ranged from 54 to 92 percent. Trinidad and Tobago's Institute for Marine Affairs estimated that more than 3,000 leatherbacks were captured incidental to gillnet fishing in the coastal waters of Trinidad in 2000. Half or more of the gravid turtles in Trinidad and Tobago waters may be killed (Lee Lum 2003), though many of the turtles do not die as a result of drowning, but rather because the fishermen butcher them in order to get them out of their nets (NMFS 2001a).

Egg collection occurs in many countries around the world (e.g., (Billes and Fretey 2004; Brautigam and Eckert 2006; Fretey et al. 2007; Hilterman and Goverse 2007; Kinan 2002; Maison et al. 2010; Santidrián Tomillo et al. 2007; Tomillo et al. 2008). For example, during the 2012 nesting season, 55% (283 of 514) of leatherback nests were poached on Pacuare Playa, Costa Rica (Fonseca and Chacon 2012). Egg harvest has been attributed to catastrophic declines such as in Malaysia. Despite conservation efforts, egg harvest continues at certain levels in Indonesia, Papua New Guinea, Solomon Islands and Vanuatu (Committee 2008). We know little about the effects of contaminants on leatherback sea turtles. The metals arsenic, cadmium, copper, mercury, selenium, and zinc bioaccumulate, with cadmium in highest concentration in

leatherbacks versus any other marine vertebrate (Caurant et al. 1999; Gordon et al. 1998). A diet of primarily jellyfish, which have high cadmium concentrations, is likely the cause (Caurant et al. 1999). Organochlorine pesticides have also been found (McKenzie et al. 1999). PCB concentrations are reportedly equivalent to those in some marine mammals, with liver and adipose levels of at least one congener being exceptionally high (PCB 209: 500-530 ng/g wet weight Davenport et al. 1990; Oros et al. 2009).

4.2.8.13 Critical Habitat

On March 23, 1979, leatherback critical habitat (See Figure Below) was identified adjacent to Sandy Point, St. Croix, U.S.V.I. from the 183 m isobath to mean high tide level between 17° 42'12" N and 65° 50'00" W (44 FR 17710). This habitat is essential for nesting, which has been increasingly threatened since 1979, when tourism increased significantly, bringing nesting habitat and people into close and frequent proximity. However, studies do not currently support significant critical habitat deterioration.

On January 26, 2012, the NMFS designated critical habitat for leatherback sea turtles in waters along Washington State and Oregon (Cape Flattery to Cape Blanco; 64,760 km^2) and California (Point Arena to Point Arguello; 43,798 km^2). The primary constituent element of these areas includes the occurrence of prey species, primarily scyphomedusae of the order Semaeostomeae (*Chrysaora, Aurelia, Phacellophora,* and *Cyanea*), of sufficient condition, distribution, diversity, abundance and density necessary to support individual as well as population growth, reproduction, and development of leatherbacks. No critical habitat is designated within the MITT Action Area for this species.

4.2.9 Loggerhead Sea Turtle

Loggerhead turtles (*Caretta caretta*) were named for their relatively large heads, which support powerful jaws and enable them to feed on hard-shelled prey, such as whelks and conch. The carapace (top shell) is slightly heart-shaped and reddish-brown in adults and sub-adults, while the plastron (bottom shell) is generally a pale yellowish color. The neck and flippers are usually dull brown to reddish brown on top and medium to pale yellow on the sides and bottom. Mean straight carapace length of adults in the southeastern U.S. is approximately 36 in (92 cm); corresponding weight is about 250 lbs (113 kg).

Loggerheads reach sexual maturity at around 35 years of age. In the southeastern U.S., mating occurs in late March to early June and females lay eggs between late April and early September. Females lay three to five nests, and sometimes more, during a single nesting season. The eggs incubate approximately two months before hatching sometime between late June and mid-November.

Hatchlings vary from light to dark brown to dark gray dorsally and lack the reddish-brown coloration of adults and juveniles. Flippers are dark gray to brown above with white to white-gray margins. The coloration of the plastron is generally yellowish to tan. At emergence, hatchlings average 1.8 in (45 mm) in length and weigh approximately 0.04 lbs (20 g).

4.2.9.1 Populations

Five groupings represent loggerhead sea turtles by major sea or ocean basin: Atlantic, Pacific, and Indian oceans, as well as Caribbean and Mediterranean seas. As with other sea turtles,

populations are frequently divided by nesting aggregation (Hutchinson and Dutton 2007). On September 22, 2011, the NMFS designated nine distinct population segments (DPSs) of loggerhead sea turtles: South Atlantic Ocean and southwest Indian Ocean as threatened as well as Mediterranean Sea, North Indian Ocean, North Pacific Ocean, northeast Atlantic Ocean, northwest Atlantic Ocean, South Pacific Ocean, and southeast Indo-Pacific Ocean as endangered (75 FR 12598). Recent ocean-basin scale genetic analysis supports this conclusion, with additional differentiation apparent based upon nesting beaches (Shamblin et al. 2014).

Pacific Ocean rookeries are limited to the western portion of the basin. These sites include Australia, New Caledonia, New Zealand, Indonesia, Japan, and the Solomon Islands.

Population structure in the Pacific is comprised of a northwestern Pacific nesting aggregation in Japan and a smaller southwestern nesting aggregation in Australia and New Caledonia (NMFS 2006e). Genetics of Japanese nesters suggest that this subpopulation is comprised of genetically distinct nesting colonies (Hatase et al. 2002a). Almost all loggerheads in the North Pacific seem to stem from Japanese nesting beaches (Bowen et al. 1995a; Resendiz et al. 1998a). The fidelity of nesting females to their nesting beach allowed differentiation of these subpopulations and the loss of nesting at a beach means a significant loss of diversity and the beach is unlikely to be recolonized (NMFS 2006e).

4.2.9.2 Distribution

Loggerheads are circumglobal, inhabiting continental shelves, bays, estuaries, and lagoons in temperate, subtropical, and tropical waters. Major nesting grounds are generally located in temperate and subtropical regions, with scattered nesting in the tropics (NMFS and USFWS 1998f). The majority of loggerhead nesting is at the western rims of the Atlantic and Indian Oceans. Nesting aggregations occur in the eastern Atlantic at Cape Verde, Greece, Libya, Turkey and along the West African Coast. The western Atlantic and Caribbean hosts nesting aggregations along the U.S. east coast from Virginia through the Florida peninsula, the Dry Tortugas and Northern Gulf of Mexico, the Bahamas, the Yucatan Peninsula, Central America and the Caribbean and into South America. Within the Indian Ocean, nesting aggregations occur at Oman, Yemen, Sri Lanka and Madagascar and South Africa. Pacific Ocean nesting sites include western and eastern Australia and Japan.

Adult loggerheads are known to make considerable migrations from nesting beaches to foraging grounds (TEWG 2009); and evidence indicates turtles entering the benthic environment undertake routine migrations along the coast that are limited by seasonal water temperatures. Small juveniles are found in pelagic waters (e.g., of the North Atlantic and the Mediterranean Sea); and the transition from oceanic to neritic juvenile stages can involve trans-oceanic migrations (Bowen et al. 2004b). Loggerhead nesting is confined to lower latitudes, concentrated in temperate zones and subtropics; the species generally does not nest in tropical areas (NMFS and USFWS 1991; NRC 1990b; Witherington et al. 2006). Loggerhead turtles travel to northern waters during spring and summer as water temperatures warm, and southward and offshore toward warmer waters in fall and winter; loggerheads are noted to occur year round in offshore waters of sufficient temperature.

4.2.9.3 Migration and Movement

Loggerhead hatchlings migrate offshore and become associated with *Sargassum* spp. habitats, driftlines, and other convergence zones (Carr 1986). After 14 to 32 years of age, they shift to a

benthic habitat, where immature individuals forage in the open ocean and coastal areas along continental shelves, bays, lagoons, and estuaries (Bowen et al. 2004a; NMFS 2001a). Adult loggerheads make lengthy migrations from nesting beaches to foraging grounds (TEWG 1998a). In the Gulf of Mexico, larger females tend to disperse more broadly after nesting than smaller individuals, which tend to stay closer to the nesting location (Girard et al. 2009). In the North Atlantic, loggerheads travel north during spring and summer as water temperatures warm and return south in fall and winter, but occur offshore year-round assuming adequate temperature. As water temperatures drop from October to December, most loggerheads emigrate from their summer developmental habitats to warmer waters south of Cape Hatteras, where they winter (Morreale and Standora 1998). For immature individuals, this movement occurs in two patterns: a north-south movement over the continental shelf with migration south of Cape Hatteras in winter and movement north along Virginia for summer foraging, and a not-so-seasonal oceanic dispersal into the Gulf Stream as far north as the 10 to 15˚ C isotherm (Mansfield et al. 2009). Wallace et al. (2009) suggested differences in growth rate based upon these foraging strategies. Long Island Sound, Core Sound, Pamlico Sound, Cape Cod Bay, and Chesapeake Bay are the most frequently used juvenile developmental habitats along the Northeast United States Continental Shelf Large Marine Ecosystem (Burke et al. 1991; Delannoy et al. 2013; Epperly et al. 1995a; Epperly et al. 1995b; Epperly et al. 1995c; Hoffman et al. 2013; Mansfield 2006). There is conflicting evidence that immature loggerheads roam the oceans in currents and eddies and mix from different natal origins or distribute on a latitudinal basis that corresponds with their natal beaches (Monzon-Arguello et al. 2009; Wallace et al. 2009). McCarthy et al. (2010) found that movement patterns of loggerhead sea turtles were more convoluted when sea surface temperatures were higher, ocean depths shallower, ocean currents stronger, and chlorophyll a levels lower. Satellite tracking of loggerheads from southeastern U.S. nesting beaches supports three dispersal modes to foraging areas: one northward along the continental shelf to the northeastern U.S., broad movement through the southeastern and mid-Atlantic U.S., and residency in areas near breeding areas (Reina et al. 2012).

Aerial surveys sponsored by the U.S. Navy January to August 2009 sighted 193 loggerhead turtles off the coast of Jacksonville, Florida, while line-transect surveys off North Carolina during the same period sighted 41 loggerhead sea turtles (Arbelo et al. 2012). Aerial observations in Onslow Bay from August 2009 through August 2010 sighted 495 loggerhead sea turtles, while vessel surveys during the same period sighted 47 loggerhead sea turtles (Ramsey 2013). Aerial surveys conducted between August 2009 and August 2010 off Jacksonville, Florida, sighted 716 loggerhead sea turtles, while vessel surveys during the same period sighted 47 loggerhead sea turtles (Ramsey 2013).

Individuals in the western Pacific also show wide-ranging movements. Loggerheads hatched on beaches in the southwest Pacific have been found to range widely in the southern portion of the basin, with individuals from populations nesting in Australia found as far east as Peruvian coast foraging areas still in the juvenile stage (Boyle et al. 2009). Individuals hatched along Japanese coasts have been found to migrate to waters off Baja California via the North Pacific Subtropical Gyre (and the Kuroshio Extension) to feed for several years before migrating back to western Pacific waters to breed (Bowen et al. 1995b; Nichols 2005; Polovina et al. 2006; Polovina et al. 2000; Resendiz et al. 1998b). Adult loggerheads also reside in oceanic waters off Japan (Hatase et al. 2002b). Habitat use off Japan may further be partitioned by sex and size (Hatase et al. 2002b; Hatase and Sakamoto 2004; Hatase et al. 2002c). Loggerheads returning to Japanese

waters seem to migrate along nutrient-rich oceanic fronts (Kobayashi et al. 2008; Nichols et al. 2000; Polovina et al. 2000). Individuals bycaught and satellite tracked in Hawaii longline fisheries show individual movement north and south within a thermal range of 15-25º C, or 28-40º N, with juveniles following the 17 to 20º C isotherm (Kobayashi et al. 2008; Nichols et al. 2000; Polovina et al. 2004). The Transition Zone Chlorophyll Front and Kuroshio Extension Current are likely important foraging areas for juvenile loggerheads (Polovina et al. 2004). The Kuroshio Current off Japan may be significant for juvenile and adult loggerheads as a wintering areas for those individuals not migrating south (Hatase et al. 2002c).

Sighting and stranding records support loggerhead sea turtles to be common, year-round residents of the Gulf of Mexico, although their abundance is much greater in the northeastern region versus the northwestern (Davis et al. 2000b; Fritts et al. 1983; Landry and Costa 1999). An estimated 12 percent of all western North Atlantic Ocean loggerhead sea turtles reside in the eastern Gulf of Mexico, with the vast majority in western Florida waters (Davis et al. 2000a; TEWG 1998b) . Loggerheads may occur in both offshore habitats (particularly around oil platforms and reefs, where prey and shelter are available; (Davis et al. 2000b; Fritts et al. 1983; Gitschlag and Herczeg 1994; Lohoefener et al. 1990; Rosman et al. 1987), as well as shallow bays and sounds (which may be important developmental habitat for late juveniles in the eastern Gulf of Mexico (Davis et al. 2000b; Lohoefener et al. 1990; USAF 1996). Offshore abundance in continental slope waters increases during the winter in the eastern Gulf of Mexico, as cooler inshore waters force individuals into warmer offshore areas (Davis et al. 2000b).

Hatchlings dispersing from Libyan shores preferentially move into the eastern Mediterranean and eventually transition into a neritic phase along southern Tunisia (Saied et al. 2012). Positive North Atlantic Oscillation phases tend to promote loggerhead presence in the western Mediterranean (Baez et al. 2014).

4.2.9.4 Growth and Reproduction

Loggerhead nesting is confined to lower latitudes temperate and subtropic zones but absent from tropical areas (NMFS and USFWS 1991b; NRC 1990a; Witherington et al. 2006b). The life cycle of loggerhead sea turtles can be divided into seven stages: eggs and hatchlings, small juveniles, large juveniles, subadults, novice breeders, first year emigrants, and mature breeders (Crouse et al. 1987). Hatchling loggerheads migrate to the ocean (to which they are drawn by near ultraviolet light Kawamura et al. 2009), where they are generally believed to lead a pelagic existence for as long as 7 to 12 years (NMFS 2005b). Based on growth rate estimates, the duration of the open-ocean juvenile stage for North Atlantic loggerhead sea is roughly 8.2 years (Bjorndal et al. 2000b). Loggerheads in the Mediterranean, similar to those in the Atlantic, grow at roughly 11.8 cm/yr for the first six months and slow to roughly 3.6 cm/yr at age 2.5 to 3.5. As adults, individuals may experience a secondary growth pulse associated with shifting into neritic habitats, although growth is generally monotypic (declines with age Casale et al. 2009a; Casale et al. 2009b). Individually-based variables likely have a high impact on individual-to-individual growth rates (Casale et al. 2009b). At 15 to 38 years, loggerhead sea turtles become sexually mature, although the age at which they reach maturity varies widely among populations (Casale et al. 2009b; Frazer and Ehrhart 1985a; Frazer et al. 1994; NMFS 2001a; Witherington et al. 2006b). However, based on new data from tag returns, strandings, and nesting surveys, NMFS (2001a) estimated ages of maturity ranging from 20 to 38 years and a benthic immature stage lasting from 14 to 32 years. Notably, data from several studies showed decreased growth rates of

loggerheads in U.S. Atlantic waters from 1997 to 2007, corresponding to a period of 43 percent decline in Florida nest counts (Bjorndal et al. 2013).

Loggerhead mating likely occurs along migration routes to nesting beaches, as well as offshore from nesting beaches several weeks prior to the onset of nesting (Dodd 1988a; NMFS and USFWS 1998d). Females usually breed every 2 to 3 years, but can vary from 1 to 7 years (Dodd 1988a; Richardson et al. 1978). Females lay an average of 4.1 nests per season (Murphy and Hopkins 1984) , although recent satellite telemetry from nesting females along southwest Florida support 5.4 nests per female per season, with increasing numbers of eggs per nest during the course of the season (Tucker 2009). The authors suggest that this finding warrants revision of the number of females nesting in the region. The western Atlantic breeding season is March-August. Nesting sites appear to be related to beaches with relatively high exposure to wind or wind-generated waves (Santana Garcon et al. 2010).

The Japanese rookeries are the most significant nesting sites for loggerheads in the North Pacific, with nesting occurring on the Japanese mainland, except for Hokkaido, as well as the Ryukyu Islands to the south (Kamezaki 1989; Kamezaki et al. 2003; Sea Turtle Association of Japan 2010; Uchida and Nishiwaki 1995). Nesting generally occurs through summer and fall (April-August, peaking in July), with females returning every two to three years (Iwamoto et al. 1985). Nesting females lay at least three nests of 60 to 115 eggs per nest each season, with roughly two weeks between nests (Eckert 1993a; Iwamoto et al. 1985; Nishimura 1994). Between nests, females appear to swim offshore into the Kuroshio Current, possibly to speed egg development (NMFS and USFWS 1998g; Sato et al. 1998).

Nesting in the Gulf of Mexico does occur, although primarily in Florida, with rare nesting along North and South Padre Island in Texas from April through September, with a peak in June and July (Dodd 1988b; Dodd Jr. 1988a; Hildebrand 1983; Weishampel et al. 2006; Williams-Walls et al. 1983).

4.2.9.5 Gender, Age, and Survivorship

Although information on males is limited, several studies identified a female bias, although a single study has found a strong male bias to be possible (Dodd 1988a; NMFS 2001a; Rees and Margaritoulis 2004). Nest temperature seems to drive sex determination. Along Florida, males primarily derive from earlier-season (LeBlanc et al. 2012). Here, nests ranged from an average sex ratio of 55 percent female to 85 percent between 2000 and 2004 (LeBlanc et al. 2012). Juvenile and adult age classes have a slight female bias in the central Mediterranean Sea of 51.5 percent (Casale et al. 2014).

Additionally, little is known about longevity, although Dodd (1988a) estimated the maximum female life span at 47 to 62 years. Heppell et al. (2003a) estimated annual survivorship to be 0.81 (southeast U.S. adult females), 0.78 to 0.91 (Australia adult females), 0.68–0.89 (southeast U.S. benthic juveniles, and 0.92 (Australia benthic juveniles). Another recent estimate suggested a survival rate of 0.41 or 0.60 (CIs 0.20 to 0.65 and 0.40 to 0.78, respectively), depending upon assumptions within the study (Sasso et al. 2011). Survival rates for hatchlings during their first year are likely very low (Heppell et al. 2003a; Heppell et al. 2003). Higher fecundity is associated with warmer February and lower May temerperatures for loggerheads on the northern Gulf of Mexico (Lamont and Fujisaki 2014).

4.2.9.6 Feeding

Loggerhead sea turtles are omnivorous and opportunistic feeders through their lifetimes (Parker et al. 2005). Hatchling loggerheads feed on macroplankton associated with *Sargassum* spp. communities (NMFS and USFWS 1991b). Pelagic and benthic juveniles forage on crabs, mollusks, jellyfish, and vegetation at or near the surface (Dodd 1988a; Wallace et al. 2009). Loggerheads in the deep, offshore waters of the western North Pacific feed on jellyfish, salps, and other gelatinous animals (Dodd Jr. 1988b; Hatase et al. 2002b). Sub-adult and adult loggerheads prey on benthic invertebrates such as gastropods, mollusks, and decapod crustaceans in hard-bottom habitats, although fish and plants are also occasionally eaten (NMFS and USFWS 1998d). Stable isotope analysis and study of organisms on turtle shells has recently shown that although a loggerhead population may feed on a variety of prey, individuals composing the population have specialized diets (Reich et al. 2010; Vander Zanden et al. 2010).

4.2.9.7 Diving

Loggerhead diving behavior varies based upon habitat, with longer surface stays in deeper habitats than in coastal ones. Off Japan, dives were shallower than 30 m (Sakamoto et al. 1993). Routine dives can last 4–172 min (Byles 1988; Renaud and Carpenter 1994; Sakamoto et al. 1990). The maximum-recorded dive depth for a post-nesting female was over 230 m, although most dives are far shallower (9–21 m (Sakamoto et al. 1990). Loggerheads tagged in the Pacific over the course of 5 months showed that about 70 percent of dives are very shallow (<5 m) and 40 percent of their time was spent within 1 m of the surface (Polovina et al. 2003; Spotila 2004b). During these dives, there were also several strong surface temperature fronts that individuals were associated with, one of 20° C at 28° N latitude and another of 17° C at 32° N latitude. In the Mediterranean, dives of over 300 min have been recorded in association with depressed water temperatures and are proposed as an overwintering strategy (Luschi et al. 2013).

4.2.9.8 Vocalization and Hearing

Sea turtles are low-frequency hearing specialists, typically hearing frequencies from 30 to 2,000 Hz, with a range of maximum sensitivity between 100 and 800 Hz (Bartol et al. 1999c; Lenhardt 1994b; Lenhardt 2002; Moein Bartol and Ketten 2006; Ridgway et al. 1969). Hearing below 80 Hz is less sensitive but still possible (Lenhardt 1994b). Bartol et al. (1999c) reported effective hearing range for juvenile loggerhead turtles is from at least 250 to 750 Hz. Both yearling and two-year old loggerheads had the lowest hearing threshold at 500 Hz (yearling: about 81 dB re 1 µPa and two-year-olds: about 86 dB re 1 µPa), with thresholds increasing rapidly above and below that frequency (Moein Bartol and Ketten 2006). Underwater tones elicited behavioral responses to frequencies between 50 and 800 Hz and auditory evoked potential responses between 100 Hz and 1,131 Hz in one adult loggerhead (Martin et al. 2012). The lowest threshold recorded in this study was 98 dB re: 1 µPa at 100 Hz. Lavender et al. (2014) found post-hatchling loggerheads responded to sounds in the range of 50 Hz to 800 Hz while juveniles responded to sounds in the range of 50 Hz to 1,000 Hz. Post-hatchlings had the greatest sensitivity to sounds at 200 Hz while juveniles had the greatest sensitivity at 800 Hz (Lavender et al. 2014).

These hearing sensitivities are similar to those reported for two terrestrial species: pond and wood turtles. Pond turtles respond best to sounds between 200 and 700 Hz, with slow declines below 100 Hz and rapid declines above 700 Hz, and almost no sensitivity above 3000 Hz (Wever

and Vernon 1956). Wood turtles are sensitive up to about 500 Hz, followed by a rapid decline above 1000 Hz and almost no responses beyond 3000 or 4000 Hz (Patterson 1966).

4.2.9.9 Status and Trends

The North Pacific DPS of loggerhead sea turtles was listed as endangered in 2011 (76 FR 58868). The global abundance of nesting female loggerhead turtles is estimated at 43,320 to 44,560 (Spotila 2004a). All loggerheads inhabiting the North Pacific Ocean are derived primarily, if not entirely, from Japanese beaches (although low level nesting may occur in areas around the South China Sea) (Chan et al. 2007). Along the Japanese coast, nine major nesting beaches (greater than 100 nests per season) and six "submajor" beaches (10 to 100 nests per season) were identified. Using information collected from these nine beaches Kamezaki et al. (2003) found a substantial decline (50 to 90 percent) in the size of the annual loggerhead nesting population over the last half of the 20th century. Also, nest count data for the last two decades suggests that the North Pacific population is "small" and lacks a robust gene pool when compared to the larger northwest Atlantic and north Indian Ocean loggerhead populations. Small populations are more susceptible to demographic variability which increases their probability of extinction. Available evidence indicates that due to loss of adult and juvenile mortalities from fishery bycatch and, to a lesser degree the loss of nesting habitat, the North Pacific loggerhead population is declining.

Snover (2008) combined nesting data from the Sea Turtle Association of Japan and data from Kamezaki et al. (2002b) to analyze an 18-year time series of nesting data from 1990 through 2007. Nesting declined from an initial peak of approximately 6,638 nests in 1990 and 1991, followed by a steep decline to a low of 2,064 nests in 1997. During the past decade, nesting increased gradually to 5,167 nests in 2005, declined and then rose again to a high of just under 11,000 nests in 2008. Estimated nest numbers for 2009 were on the order of 7,000 to 8,000 nests. While nesting numbers have gradually increased in recent years and the number for 2009 was similar to the start of the time series in 1990, historical evidence from Kamouda Beach (census data dates back to the 1950s) indicates that there has been a substantial decline over the last half of the 20th century (Kamezaki et al. 2003) and that current nesting represents a fraction of historical nesting levels.

In addition, loggerheads uncommonly occur in U.S. Pacific waters, and there were no documented strandings of loggerheads on the Hawaiian Islands in nearly 20 years (1982 to 1999 stranding data). There are very few records of loggerheads nesting on any of the many islands of the central Pacific, and the species is considered rare or vagrant in this region (USFWS 1998). Overall, Gilman (2009) estimated that the number of loggerheads nesting the Pacific has declined by 80 percent in the past 20 years.

The Navy's NMSDD estimates 0.000022 loggerhead sea turtles per km^2 in the MITT Action Area (DoN 2014).

4.2.9.10 Natural Threats

Sea turtles face predation primarily by sharks and to a lesser extent by killer whales. All sea turtles except leatherbacks can undergo "cold stunning" if water temperatures drop below a threshold level, which can pose lethal effects. In January 2010, an unusually large cold-stunning event occurred throughout the southeast U.S., with well over 3,000 sea turtles (mostly greens but

also hundreds of loggerheads) found cold-stunned. Most survived, but several hundred were found dead or died after being discovered in a cold-stunned state. Eggs are commonly eaten by raccoons and ghost crabs along the eastern U.S. (Barton and Roth 2008). In the water, hatchlings are hunted by herons, gulls, dogfish, and sharks. Heavy loads of barnacles are associated with unhealthy or dead stranded loggerheads (Deem et al. 2009). Brevetoxin-producing algal blooms can result in loggerhead sea turtle death and pathology, with nearly all stranded loggerheads in affected areas showing signs of illness or death resulting from exposure (Fauquier et al. 2013). The fungal pathogens *Fusarium falciforme* and *F. keratoplasticum* an kill in excess of 90 percent of sea turtle embryos they infect and may constitute a major threat to nesting productivity under some conditions (Sarmiento-Ramırez et al. 2014).

4.2.9.11 Anthropogenic Threats

Anthropogenic threats impacting loggerhead nesting habitat are numerous: coastal development and construction, placement of erosion control structures, beachfront lighting, vehicular and pedestrian traffic, sand extraction, beach erosion, beach nourishment, beach pollution, removal of native vegetation, and planting of non-native vegetation (Baldwin 1992; Margaritoulis et al. 2003; Mazaris et al. 2009b; USFWS 1998). Surprisingly, beach nourishment also hampers nesting success, but only in the first year post-nourishment before hatching success increases (Brock et al. 2009). Loggerhead sea turtles face numerous threats in the marine environment as well, including oil and gas exploration, marine pollution, trawl, purse seine, hook and line, gill net, pound net, longline, and trap fisheries, underwater explosions, dredging, offshore artificial lighting, power plant entrapment, entanglement in debris, ingestion of marine debris, marina and dock construction and operation, boat collisions, and poaching. At least in the Mediterannean Sea, Anthorpogenic threats appear to disproportionally impact larger (more fecund) loggerheads (Bellido et al. 2010).

The major factors inhibiting their recovery include mortalities caused by fishery interactions and degradation of the beaches on which they nest. Shrimp trawl fisheries account for the highest number of captured and killed loggerhead sea turtles. Along the Atlantic coast of the U.S., the NMFS estimated that shrimp trawls capture almost 163,000 loggerhead sea turtles each year in the Gulf of Mexico, of which 3,948 die. However, more recent estimates from suggest interactions and mortality has decreased from pre-regulatory periods, with a conservative estimate of 26,500 loggerheads captured annually in U.S. Atlantic fisheries causing mortality up to 1,400 individuals per year (Finkbeiner et al. 2011). Commercial gillnet fisheries are estimated to have killed 52 loggerheads annually along the U.S. mid-Atlantic (Murray 2013). Pacific bycatch is much less, with about 400 individuals bycaught annually in U.S. fisheries resulting in at least 20 mortalities (Finkbeiner et al. 2011). Each year, various fisheries capture about 2,000 loggerhead sea turtles in Pamlico Sound, of which almost 700 die. As a result of the 2006 and 2007 tri-national fishermen's exchanges in 2007 a prominent Baja California Sur fleet retired its bottom-set longlines (Peckham et al. 2008). Prior to this closure, the longline fleet interacted with an estimated 1,160 to 2,174 loggerheads annually, with nearly all (89 percent) of the takes resulting in mortalities (Peckham et al. 2008).

Offshore longline tuna and swordfish longline fisheries are also a serious concern for the survival and recovery of loggerhead sea turtles and appear to affect the largest individuals more than younger age classes (Aguilar et al. 1995; Bolten et al. 1994; Carruthers et al. 2009; Howell et al. 2008; Marshall et al. 2009; Petersen et al. 2009; Tomás et al. 2008). In the Pacific Ocean,

between 2,600 and 6,000 loggerhead sea turtles are estimated to have been captured and killed in longline fisheries in 2000 (Lewison et al. 2004). Shallow-set Hawaii based longline fisheries are estimated to have captured and killed several hundred loggerhead sea turtles before they were closed in 2001. When they were re-opened in 2004, with substantial modifications to protect sea turtles, these fisheries were estimated to have captured and killed about fewer than 5 loggerhead sea turtles each year. Between 2004 and 2008, shallow-set fisheries based out of Hawaii are estimated to have captured about 45 loggerhead sea turtles, killing about 10 of these sea turtles. Longline hooking along Hawaii and California suggests a 28 percent mortality rate for hooked and released loggerheads, with no significant difference between shallow- versus deep-hooked individuals (Swimmer et al. 2013). Deliberate hunting of loggerheads for their meat, shells, and eggs has declined from previous exploitation levels, but still exists and hampers recovery efforts (Lino et al. 2010). (Lino et al. 2010). Roughly 10,000 loggerheads are bycaught by longline fisheries in the southwestern Mediterranean annually (Àlvarez de Quevedo et al. 2013). Of these, from 30 to 40 percent are expected to die, resulting in 3,400-4,000 deaths per year, or about 10 percent of the loggerheads present in the region (Àlvarez de Quevedo et al. 2013). In the Pacific, loggerhead turtles are captured, injured, or killed in numerous Pacific fisheries including Japanese longline fisheries in the western Pacific Ocean and South China Seas direct harvest and commercial fisheries off Baja California, Mexico commercial and artisanal swordfish fisheries off Chile, Columbia, Ecuador, and Peru purse seine fisheries for tuna in the eastern tropical Pacific Ocean California/Oregon drift gillnet fisheries (NMFS 2006e). Wallace et al. (2010) estimated that between 1990 and 2008, at least 85,000 sea turtles were captured as bycatch in fisheries worldwide. This estimate is likely at least two orders of magnitude low, resulting in a likely bycatch of nearly half a million sea turtles annually (Wallace et al. 2010c); many of these are expected to be loggerhead sea turtles.

Marine debris ingestion can be a widespread issue for loggerhead sea turtles. More than one-third of loggerheads found stranded or bycaught had ingested marine debris in a Mediterranean study, with possible mortality resulting in some cases (Lazar and Gračan 2010). Another study in the Tyrrhenian Sea found 71 percent of stranded and bycaught sea turtles had plastic debris in their guts (Campani et al. 2013). Another threat marine debris poses is to hatchlings on beaches escaping to the sea. Two thirds of loggerheads contacted marine debris on their way to the ocean and many became severely entangled or entrapped by it (Triessnig et al. 2012).

Climate change may also have significant implications on loggerhead populations worldwide. In addition to potential loss of nesting habitat due to sea level rise, loggerhead sea turtles are very sensitive to temperature as a determinant of sex while incubating. Ambient temperature increase by just 1 to 2º C can potentially change hatchling sex ratios to all or nearly all female in tropical and subtropical areas (Hawkes et al. 2007a). Over time, this can reduce genetic diversity, or even population viability, if males become a small proportion of populations (Hulin et al. 2009). Sea surface temperatures on loggerhead foraging grounds correlate to the timing of nesting, with higher temperatures leading to earlier nesting (Mazaris et al. 2009a; Schofield et al. 2009). Increasing ocean temperatures may also lead to reduced primary productivity and eventual food availability. This has been proposed as partial support for reduced nesting abundance for loggerhead sea turtles in Japan; a finding that could have broader implications for other populations in the future if individuals do not shift feeding habitat (Chaloupka et al. 2008c). Warmer temperatures may also decrease the energy needs of a developing embryo (Reid et al. 2009). Pike (2014) estimated that loggerhead populations in tropical areas produce about 30

percent fewer hatchlings than do populations in temperate areas. Historical climactic patterns have been attributed to the decline in loggerhead nesting in Florida, but evidence for this is tenuous (Reina et al. 2013).

Tissues taken from loggerheads sometimes contain very high levels of organochlorines chlorobiphenyl, chlordanes, lindane, endrin, endosulfan, dieldrin, PFOS, PFOA, DDT, and PCB (Alava et al. 2006; Corsolini et al. 2000; Gardner et al. 2003; Keller et al. 2005; Keller et al. 2004a; Keller et al. 2004b; McKenzie et al. 1999; Monagas et al. 2008; Oros et al. 2009; Perugini et al. 2006; Rybitski et al. 1995; Storelli et al. 2007a). It appears that levels of organochlorines have the potential to suppress the immune system of loggerhead sea turtles and may affect metabolic regulation (Keller et al. 2004c; Keller et al. 2006b; Oros et al. 2009). These contaminants could cause deficiencies in endocrine, developmental, and reproductive health (Storelli et al. 2007a). It is likely that the omnivorous nature of loggerheads makes them more prone to bioaccumulating toxins than other sea turtle species (Godley et al. 1999; McKenzie et al. 1999). PAH pollution from petroleum origins has been found in Cape Verde loggerheads, where oil and gas extraction is not undertaken in the marine environment (Camacho et al. 2012).

Heavy metals, including arsenic, barium, cadmium, chromium, iron, lead, nickel, selenium, silver, copper, zinc, and manganese, have also been found in a variety of tissues in levels that increase with turtle size (Anan et al. 2001; Fujihara et al. 2003; Garcia-Fernandez et al. 2009; Gardner et al. 2006; Godley et al. 1999; Saeki et al. 2000; Storelli et al. 2008). These metals likely originate from plants and seem to have high transfer coefficients (Anan et al. 2001; Celik et al. 2006; Talavera-Saenz et al. 2007). Elevated mercury levels are associated with deformities in hatchlings versus healthy individuals (Trocini 2013). Loggerhead sea turtles have higher mercury levels than any other sea turtle studied, but concentrations are an order of magnitude less than many toothed whales (Godley et al. 1999; Pugh and Becker 2001). Arsenic occurs at levels several fold more concentrated in loggerhead sea turtles than marine mammals or seabirds.

Also of concern is the spread of antimicrobial agents from human society into the marine environment. Loggerhead sea turtles may harbor antibiotic-resistant bacteria, which may have developed and thrived as a result of high use and discharge of antimicrobial agents into freshwater and marine ecosystems (Foti et al. 2009).

4.2.9.12 Critical Habitat

On July 10, 2014, NMFS designated critical habitat for loggerhead sea turtles along the U.S. Atlantic and Gulf of Mexico coasts from North Carolina to Mississippi (79 FR 39856). No critical habitat is designated within the MITT Action Area for this species.

4.2.10 Scalloped Hammerhead Shark – Indo-West Pacific DPS

Scalloped hammerhead sharks are moderately large sharks with a flat, laterally extended head with a scalloped anterior margin. Unless otherwise noted, the information presented below was obtained from the Status Review Report for the Scalloped Hammerhead Shark (*Sphyrna lewini*) (Miller et al. 2014).

4.2.10.1 Populations

On July, 3, 2014 NMFS issued the final determination to list the Central and Southwest (SW) Atlantic Distinct Population Segment (DPS) and the Indo-West Pacific DPS of scalloped

hammerhead shark (*Sphyrna lewini*) as threatened species under the Endangered Species Act (ESA) (79 FR 38213). NMFS also issued a final determination to list the Eastern Atlantic DPS and Eastern Pacific DPS of scalloped hammerhead sharks as endangered species under the ESA (79 FR 38213). Populations are generally delineated by ocean basins based on discrete differences in genetic structure and limited transoceanic migrations of this species.

4.2.10.2 Distribution

The scalloped hammerhead shark can be found in coastal warm temperate and tropical seas worldwide. In the western Atlantic Ocean the scalloped hammerhead range extends from the northeast coast of the United States to Brazil, including the Gulf of Mexico and the Caribbean Sea. In the eastern Atlantic, it can be found from the Mediterranean to Namibia. Populations in the Indian Ocean are found from South Africa to Pakistan, India and Myanmar. In the western Pacific the scalloped hammerhead can be found from Japan and China to New Caledonia, including throughout the Philippines, Indonesia, Australia, and the U.S. territorial islands. In the eastern Pacific the scalloped hammerhead can be found southern California to Peru, including the Gulf of California. In the central pacific the scalloped hammerhead can be found in Hawaii and Tahiti.

4.2.10.3 Migration and movement

Scalloped hammerhead sharks are highly mobile and partly migratory. Along continental margins and between oceanic islands in tropical waters migration is common. Adult migratory movements are generally less than 200 km but this species is also capable of moving much greater distances up to approximately 2,000 km. Juvenile movements are likely much shorter. Juveniles and adults occur as solitary individuals, pairs, or in schools and there is evidence of site fidelity to known hot spots.

4.2.10.4 Habitat

Scalloped hammerhead sharks primarily occur over continental and insular shelves and rarely in waters cooler than 22° C. It ranges from surface waters to depths of 512 m with occasional dives to deeper water up to 1000 m. It is also known to occur in bays and estuaries. Neonates and juveniles aggregations are more common in nearshore nursery habitats that may provide valuable refuge from predation. Anecdotal information suggests that Guam's inner Apra Harbor could provide nursery habitat for this species (Miller et al. 2014). Scalloped hammerhead sharks appear to prefer areas with stronger currents, greater turbidity, and higher sedimentation and nutrient flow.

4.2.10.5 Growth and reproduction

The scalloped hammerhead shark is viviparous (i.e., give birth to live young), with a gestation period of 9 to 12 months. Females attain sexual maturity at 200 to 250 cm total length (TL) while males reach maturity at 128 to 200 cm TL. Maturity times vary regionally but can range from 4 to 15 years for females and 3.8 to 10 years for males. Parturition likely occurs inshore with peak neonate abundance occurring during the spring and summer. Females give birth to litter sizes up to 41 live pups measuring 31 to 59 cm TL. Maximum size for females and males is over 3 m TL and a maximum age up to 30 years.

4.2.10.6 Feeding

Scalloped hammerhead sharks are high trophic level predators and opportunistic feeders with a diet including teleosts, cephalopods, crustaceans, and rays. Juvenile sharks in Kāneohe Bay, Hawaii were observed to feed primarily at night. Feeding occurs both at reef sites and in pelagic waters.

4.2.10.7 Vocalization and hearing

Scalloped hammerhead sharks, like all fish, have an inner ear capable of detecting high-frequency sounds and a lateral line capable of detecting water motion caused by low frequencies (Hastings and Popper 2005; Popper and Schilt 2009). Data for cartilaginous fish suggest detection of sounds from 20 Hz to 1000 Hz with the highest sensitivity to sounds at the lower ranges (Casper et al. 2003; Casper and Mann 2006; Myrberg Jr. 2001).

4.2.10.8 Status and trends

The Final Rule to list the Central SW Atlantic DPS, Eastern Atlantic DPS, Indo-West Pacific DPS, and the Eastern Pacific DPS (79 FR 38213) and the Status Review Report (Miller et al. 2014) provide detailed discussion of the status of each DPS. Logistic and Fox modeling efforts using the best available data suggest a decrease in global abundance from 142,000 and 169,000 individuals (respectively by model) in 1981 to 24,850 and 27,900 individuals (respectively) in 2005. This represents an 83 percent decrease in global abundance based on both the logistic and Fox models over a 15 year period.

The Indo-West Pacific DPS of scalloped hammerhead sharks is listed as threatened and no take prohibitions have been implemented (79 FR 38213). For the Indo-West Pacific DPS, commercial and artisanal fisheries were identified as a high risk to the extinction due to targeted catch and bycatch. The inadequacy of current regulatory mechanisms was also identified as a moderate risk, with illegal fishing significantly contributing to the DPS' risk of extinction. Multiple Regional Fishery Management Organizations (RFMO) cover the Indo-West Pacific DPS area with requirements of full utilization of any retained catches of sharks and regulations that onboard fins cannot weigh more than 5 percent of the weight of the sharks. These regulations are aimed at curbing the practice of shark finning, but do not prohibit the fishing of sharks. In addition, these regulations may not even be effective in stopping finning of scalloped hammerhead sharks, as a recent study found the scalloped hammerhead shark to have an average wet-fin-to-round-mass ratio of only 2.13 percent (n = 81; (Biery and Pauly 2012). This ratio suggests that fishing vessels operating in these RFMO convention areas would be able to land more scalloped hammerhead shark fins than bodies and still pass inspection. There are no scalloped hammerhead-specific RFMO management measures in place for this region, even though this DPS is heavily fished. Consequently, this species has seen population declines off the coasts of South Africa and Australia, so much so that in 2012, New South Wales, Australia, listed it as an endangered species.

Few countries within this DPS' range have regulations aimed at controlling the exploitation of shark species. Oman, Seychelles, Australia, South Africa, Taiwan, and most recently India all have measures to prevent the waste of shark parts and discourage finning. The Maldives have designated their waters as a shark sanctuary. A number of Pacific Island countries (including U.S. territories) have also created shark sanctuaries, prohibited shark fishing, or have strong management measures to control the exploitation of sharks in their respective waters, including

Tokelau, Palau, Marshall Islands, American Samoa, CNMI, Cook Islands, and French Polynesia, although effective enforcement of these regulations is an issue for some of the countries. Additionally, many of the top shark fishing nations and world's exporters of fins are also located within the range of this DPS, and have little to no regulation (or enforcement) of their expansive shark fisheries. For example, off northern Madagascar, where there is an active artisanal fin fishery, sharks are an open access resource, with no restrictions on gear, established quotas, or fishing area closures (Robinson and Sauer 2011). Indonesia, which is the top shark fishing nation in the world, does not currently have restrictions pertaining to shark fishing or finning. Indonesian small-scale fisheries, which account for around 90 percent of the total fisheries production, are not required to have fishing permits (Varkey et al. 2010), nor are their vessels likely to have insulated fish holds or refrigeration units (Tull 2009), increasing the incentive for shark finning by this sector (Lack and Sant 2012). Ultimately, their fishing activities remain largely unreported (Varkey et al. 2010), which suggests that the estimates of Indonesian shark catches are greatly underestimated. In fact, in Raja Ampat, an archipelago in Eastern Indonesia, Varkey et al. (2010)estimated that 44 percent of the total shark catch in 2006 was unreported (including small-scale and commercial fisheries' unreported catch and illegal, unregulated, and unreported (IUU) fishing). Although Indonesia adopted an FAO recommended shark conservation plan (National Plan of Action—Shark) in 2010, due to budget constraints, it can only focus its implementation of key conservation actions in one area, East Lombok (Satria et al. 2011). Due to this historical and current absence of shark management measures, especially in the small-scale fisheries sector, many of the larger shark species in Indonesian waters have already been severely overfished (Field et al. 2009).

In addition to the largely unregulated fishing of this DPS, illegal fishing, especially for shark fins, has been identified as a significant contributor to the extinction risk of this DPS. Scalloped hammerhead sharks are valued for their large fins, which fetch a high commercial value in the Asian shark fin trade (Abercrombie et al. 2005)and comprise the second most traded fin category in the Hong Kong market (Clarke et al. 2006). Due to this profit incentive, there have been many reports of finning and seizures of illegally gained shark fins throughout the range of this DPS, including inwaters of Australia (Field et al. 2009), Mozambique, South Africa, Bay of Bengal, Arabian Gulf, Palau, the Federated States of Micronesia (FSM) (Paul 2009), and Somalia (Force 2006). Agnew et al. (2009)provided regional estimates of illegal fishing (using FAO fishing areas as regions) and found the Western Central Pacific (Area 71) and Eastern Indian Ocean (Area 57) regions to have relatively high levels of illegal fishing (compared to the rest of the regions), with illegal and unreported catch constituting 34 and 32 percent of the region's catch, respectively.

Off the coast of Oman, scalloped hammerhead sharks experienced a notable decline in abundance in 2003 and is apparently being replaced by smaller elasmobranch species and smaller individuals of the same species, a trend that may be occurring in other areas as well (Henderson et al. 2007). Declines in abundance in Indonesia may also be occurring as catch in longline fisheries has decreased from 15 to 2 percent from 2001 to 2011 (FAO 2013). In contrast, catch off of the coast of India suggest a potential increase in abundance, although scalloped hammerhead shark size appears to be decreasing (CITES 2012). Data from Australia indicates a decline of 58 to 76 percent from 1996 to 2005 along Northern Australia (Heupel and McAuley 2007) and a decline of more than 90 percent from 1973 to 2008 along New South Wales (Reid

and Krogh 1992; Williamson 2011). In the coastal waters of Papau New Guinea scalloped hammerhead catch decreased by 43 percent from 2011 to 2012 (De Young 2006).

Although the number of shark management and conservation measures for this DPS is on the rise, the NMFS Extinction Risk Analysis team noted that the current protections that they afford the Indo-West Pacific DPS may be minimal if illegal fishing is not controlled. We agree and conclude that the inadequacy of current regulatory mechanisms, in the form of ineffective enforcement of current regulations or lack of existing regulatory measures, in combination with illegal fishing, is contributing significantly to the risk of extinction of this DPS.

4.2.10.9 Natural threats

While not actually threats, natural factors such as the lengthy age to sexual maturity, relatively small maximum size, and obligate ram ventilation systems of this species makes them particularly vulnerable to depletion and slow recovery from anthropogenic threats.

4.2.10.10 Anthropogenic threats

The Final Rule to list the Central SW Atlantic DPS, Eastern Atlantic DPS, Indo-West Pacific DPS, and the Eastern Pacific DPS (79 FR 38213) and the Status Review Report (Miller et al. 2014) provide detailed discussion of the threats to each DPS. As described in the Rule, the primary factors responsible for the decline of these four DPSs are overutilization, due to both catch and bycatch of these sharks in fisheries, and inadequate regulatory mechanisms for protecting these sharks, with illegal fishing identified as a significant problem.

4.2.10.11 Critical habitat

The NMFS has not designated critical habitat for scalloped hammerhead sharks.

4.2.11 Acropora globiceps

Colonies of *Acropora globiceps* have finger-like branches. The size and appearance of branches depend on degree of exposure to wave action but are always closely compacted. Colonies exposed to strong wave action have pyramid-shaped branchlets. Colonies can be uniform blue, cream, brown, or fluorescent green in color. *Acropora globiceps* can easily be confused with other *Acropora* species due to both colony and branch morphology, as colonies often appear similar to *Acropora gemmifera*, and in strong wave action colonies appear similar to *Acropora monticulosa*. In addition, *Acropora globiceps*' branch thickness and colony shape are similar to that of *Acropora humilis*, and its branch shape and radial corallite morphology is similar to that of *Acropora samoensis*. It appears that this species has often been mistaken for *A. humilis* (Fenner 2014). However, Veron (2014) states that *Acropora globiceps* is distinctive, and the final rule concluded that it can be identified by experts (79 FR 53852).

4.2.11.1 Distribution and Abundance

Acropora globiceps is distributed from the oceanic west Pacific to the central Pacific as far east as the Pitcairn Islands. Veron (2014) reported that *Acropora globiceps* is confirmed in 22 of his 133 Indo-Pacific ecoregions, and strongly predicted to be found in an additional 16. Wallace (1999a) reports its occurrence in seven of her 29 Indo-Pacific areas, many of which are significantly larger than Veron's ecoregions. The map presented in Wallace (1999a) shows it from a smaller area than Veron (Veron, 2000; Veron, 2014). Based on the Wallace (1999a) range, *Acropora globiceps* has a relatively small range, estimated at 5 million km^2 (Richards

2009). Within U.S. waters, this species is confirmed in American Samoa, Guam, CNMI, and PRIAs (http://www.fpir.noaa.gov/PRD/prd_coral.html).

Veron (2014) reports that *Acropora globiceps* occupied 3.2 percent of 2,984 dive sites sampled in 30 ecoregions of the Indo-Pacific, and had a mean abundance rating of 1.95 on a 1 to 5 rating scale at those sites in which it was found. Based on this semi-quantitative system, the species' abundance was characterized as ''uncommon.'' Overall abundance was described as ''sometimes common.'' Veron did not infer trends in abundance from these data. According to the Final Rule (79 FR 53852) *Acropora globiceps*' absolute abundance is at least tens of millions of colonies at the time of listing.

Within the Mariana Islands, *Acropora globiceps* is confirmed in both Guam and CNMI (NMFS 2015 "Listed Corals in the Indo-Pacific: *Acropora globiceps*, 4 p." [this is a species report posted on our coral page]). On Guam, a recent review of available coral survey data from numerous sites around the island showed *Acropora globiceps* at dozens of locations around the island. Several surveys were conducted within Apra Harbor, but the species was not found there (NMFS/PIRO/HCD Guam coral database, 2015). In CNMI, coral survey data shows *Acropora globiceps* on reef slopes around Rota, Tinian, Saipan, Pagan, Anatahan, and Maug (Doug Fenner, personal communication, 2015). It has also been observed in low abundances around FDM (DoN 2005a). *Acropora globiceps* is by far the most common ESA-listed coral species in the Mariana Islands.

4.2.11.2 Habitat

Acropora globiceps inhabits intertidal, upper reef slopes and reef flats (Veron 2000). It is reported from depths of 0 to 8 m (Veron 2000).

4.2.11.3 Reproduction and Growth

Acropora are sessile colonies that spawn their gametes into the water column, and the azooxanthellate larvae can survive in the planktonic stage from 4 to 209 days. All species of the genus *Acropora* studied to date are simultaneous hermaphrodites, with a gametogenic cycle in which eggs develop over a period of about 9 months and testes over about 10 weeks. Fecundity in *Acropora* colonies is generally described as ranging from 3.6 to 15.8 eggs per polyp. Mature eggs of species of *Acropora* are large when compared with those of other corals, ranging from 0.53 to 0.90 mm in mean diameter. For five *Acropora* species, the minimum reproductive size ranged from 4 to 7 cm, and the estimated ages ranged from 3 to 5 years (Brainard et al. 2011b).

Acropora globiceps is a hermaphroditic spawner with lecithotrophic (yolk-sac) larvae (79 FR 53852). *Acropora* spp. release gametes as egg-sperm bundles that float to the sea surface, each polyp releasing all its eggs and sperm in one bundle. Fertilization takes place after the bundles break open at the sea surface. Sperm concentrations of 10^6 ml^{-1} have been found to be optimal for fertilization in the laboratory, and concentrations of this order have been recorded in the field during mass spawning events. Self-fertilization, although possible, is infrequent. Gametes remain viable and achieve high fertilization rates for up to 8 hours after spawning. Embryogenesis takes place over several hours, and further development leads to a planula that is competent to settle in 4 to 5 days after fertilization. *Acropora* spp. can show a high degree of hybridization, which can complicate taxonomic classification but allow persistence of the genus if the hybrids are reproductively viable (Brainard et al. 2011).

Larvae presumably experience considerable mortality (up to 90 percent or more) from predation or other factors prior to settlement and metamorphosis (NMFS 2014). Such mortality cannot be directly observed, but is inferred from the large amount of eggs and sperm spawned versus the much smaller number of recruits observed later. Coral larvae are relatively poor swimmers; therefore, their dispersal distances largely depend on the duration of the pelagic phase and the speed and direction of water currents transporting the larvae. The potential for long-term dispersal of coral larvae, at least for some species, may be substantially greater than previously understood and may partially explain the large geographic ranges of many species (NMFS 2014).

The tissue thickness of *Acropora* species is 1 to 2 mm thick, considerably thinner than many coral species, which allows them to grow quicker (Loya et al. 2001). The smaller reserve of nutrients in the thin layer of tissue also makes *Acropora* species more susceptible to environmental distrurbance (Grottoli et al. 2004; Rodrigues and Grottoli 2007; Rodrigues et al. 2008). *Acropora* species generally reach sexual maturity at 4 to 7 cm or roughly 3 to 5 years of age (Wallace 1985).

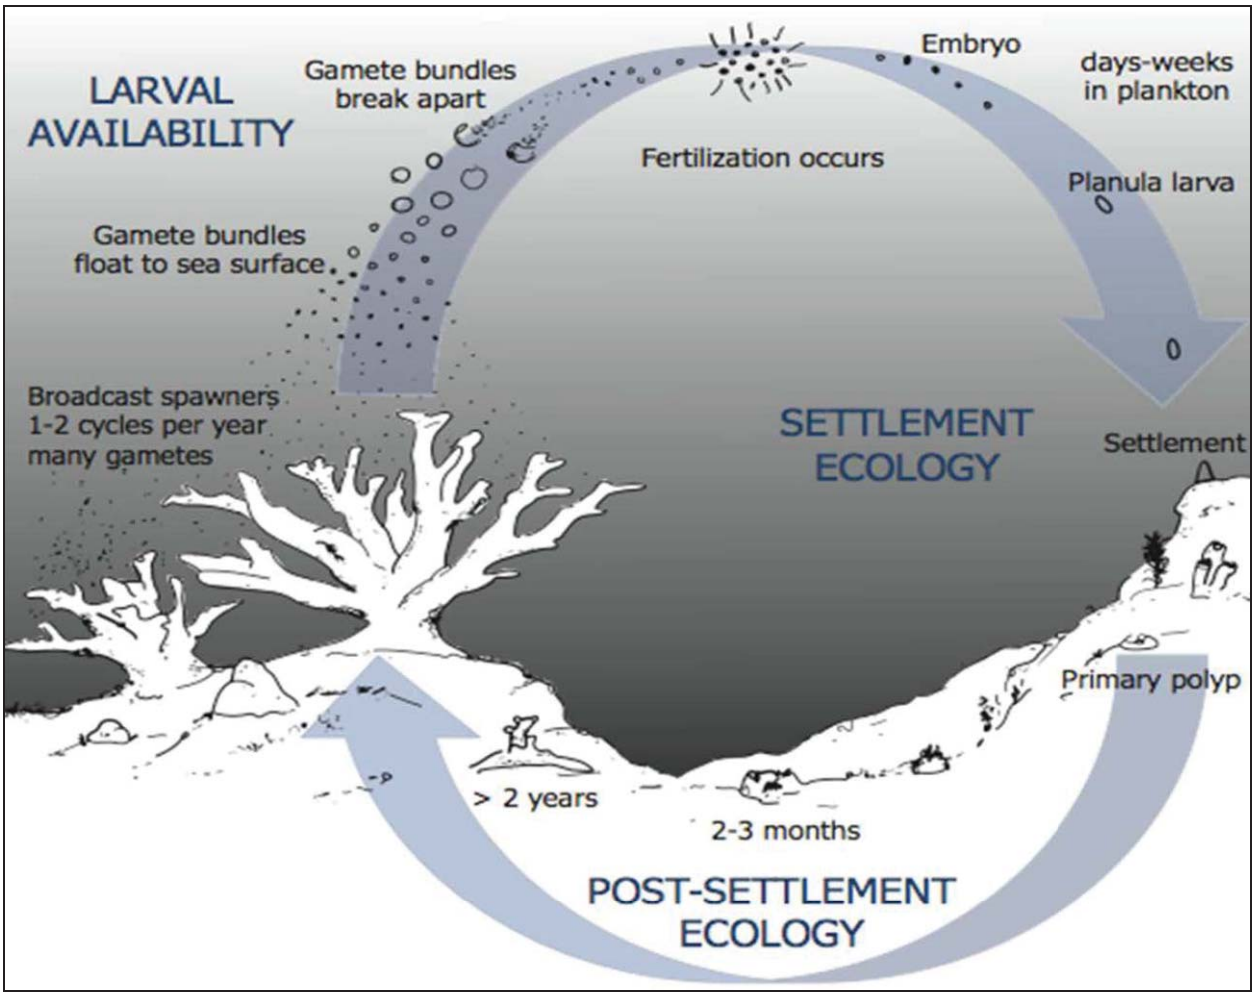

Figure 15. Typical Life Cycle of Broadcast Spawning Corals

4.2.11.4 Status and trends

Acropora globiceps was listed as threatened on September 10, 2014 (79 FR 53851). The abundance of *Acropora globiceps* has likely declined over the past 50 to 100 years although a

precise quantification is not possible based on the limited species specific information. The species is highly susceptible to ocean warming, and is susceptible to coral disease, ocean acidification, trophic effects of fishing, nutrients over-enrichment, and predation, all of which have increased in the past 50 to 100 years, and continue to increase throughout much of its range. *Acropora globiceps*' geographic distribution includes the Coral Triangle, but also includes many coral reef ecoregions in the western and central Pacific Ocean, as far east as the Pitcairn Islands. Its depth range is at least zero to 8 meters in upper reef slopes, reef flats, and adjacent habitats. Its absolute abundance is at least tens of millions of colonies across its range. While spatial variability of threats such as ocean warming and acidification across the species' range moderates vulnerability because many colonies are either not exposed to threats or do not negatively respond to a threat at any given point in time, the threats are increasing and will continue to increase in the foreseeable future, thus the species is expected to continue to decline. However, there is inadequate data to quantify current and future population status and trends on any spatial scale, let alone across the range of the speces (79 FR 53852).

4.2.11.5 Natural threats

Of the nine primary threats to reef-building corals (ocean warming, coral disease, ocean acidification, sedimentation, nutrients, trophic effects of fishing, sea-level rise, predation, and collection and trade), only predation is considered a natural threat. Due to the lack of species-specific information on the susceptibility of *Acropora globiceps* to predation, we summarize the available information on this threat to *Acropora* species in general: The studies cited in the Status Review Report (Brainard et al. 2011b) and Final Rule (79 FR 53852) on predation in *Acropora* report that predators such as crown-of-thorns starfish and *Drupella* snails prefer to eat *Acropora* over other genera. Thus, the available information suggests that *Acropora globiceps* is likely to have some susceptibility to predation (79 FR 53852).

4.2.11.6 Anthropogenic threats

Of the nine primary threats to reef-building corals (ocean warming, coral disease, ocean acidification, sedimentation, nutrients, trophic effects of fishing, sea-level rise, predation, and collection and trade), all but predation are considered anthropogenic threats. Due to the lack of species-specific information on the susceptibilities of *Acropora globiceps* to these threats, we summarize the available information for *Acropora* species in general.

Based on the information from the Status Review Report (Brainard et al. 2011b) and Final Rule (79 FR 53852), we make the following inferences regarding the susceptibilities of an unstudied *Acropora* species to these eight anthropogenic threats. For ocean warming, nearly all the studies cited on thermal stress in *Acropora* report high levels of bleaching in response to warming events. Thus, it is possible to predict that an unstudied *Acropora* species is likely to be highly susceptible to warming-induced bleaching, as long as some considerations are kept in mind: (1) Despite high overall susceptibility within the genus to warming-induced bleaching, there can be high variability between species and habitats (Done et al. 2003); (2) colonies that bleach do not necessarily die (in general, *Acropora* species have higher post-bleaching mortality than corals as a whole, but there is high variability in response throughout the genus); (3) recovery from bleaching provides the mechanism for acclimatization; and (4) while most *Acropora* species readily bleach in response to warming events, most also have the capacity to reestablish local populations relatively quickly through their rapid growth and asexual reproduction capacity.

Diseases are generally more common in *Acropora* than other coral genera, although there are numerous documented exceptions, depending on location. These studies also demonstrate high variability in disease susceptibility across *Acropora* species, depending on growth form, with wide divergence of disease susceptibilities among colony morphological groups under the same conditions. Thus, it is possible to predict that an unstudied *Acropora* species is likely to have some susceptibility to disease. The studies cited above on ocean acidification in *Acropora* report impacts on skeletal growth rates. Thus, it is possible to predict that an unstudied *Acropora* species is likely to have some susceptibility to ocean acidification in terms of impacts on skeletal growth. Most studies on the effects of land-based sources of pollution suggest that an unstudied *Acropora* species is likely to have some susceptibility to sedimentation and nutrient enrichment. The trophic effects of fishing alters trophic interactions by reducing herbivory on algae by removal of herbivorous fish from coral reef systems by fishing, thereby providing a competitive advantage for space to algae over coral. An unstudied *Acropora* species is likely to have some susceptibility to the trophic effects of fishing. Because *Acropora* are not generally sediment-tolerant and are faster growing species, an unstudied *Acropora* species is likely to have some susceptibility to sea-level rise. Because *Acropora* species are some of the most popular coral species to collect and trade, an unstudied *Acropora* species is likely to have some susceptibility to collection and trade.

According to the Status Review Report (Brainard et al. 2011b) and Final Rule (79 FR 53852), there is little if any species-specific information on the susceptibilities of *Acropora globiceps* to threats. However, based on genus-level information, we infer that *Acropora globiceps* is likely to be highly susceptible to ocean warming and to have some susceptibility to disease, acidification, sedimentation, nutrients, trophic effects of fishing, sea-level rise, and collection and trade (79 FR 53852).

4.2.11.7 Critical habitat

The NMFS has not designated critical habitat for *Acropora globiceps*.

5 ENVIRONMENTAL BASELINE

By regulation, environmental baselines for biological opinions include the past and present impacts of all state, Federal, or private actions and other human activities in the Action Area, the anticipated impacts of all proposed Federal projects in the Action Area that have already undergone formal or early section 7 consultation, and the impact of State or private actions which are contemporaneous with the consultation in process (50 CFR § 402.02). The environmental baseline for this Opinion includes the effects of several activities that affect the survival and recovery of ESA-listed resources in the Action Area.

The following information summarizes the principal natural and human-caused phenomena in the MITT Action Area believed to affect the survival and recovery of these species in the wild.

5.1 Climate Change

The latest Assessment Synthesis Report from the Working Groups on the Intergovernmental Panel on Climate Change (IPCC) concluded climate change is unequivocal (IPCC 2014). The Report concludes oceans have warmed, with ocean warming the greatest near the surface (e.g., the upper 75 m have warmed by 0.11 ^{o}C per decade over the period 1971 to 2010) (IPCC 2014).

Global mean sea level rose by 0.19 m between 1901 and 2010, and the rate of sea-level rise since the mid-19th century has been greater than the mean rate during the previous two millennia (IPCC 2014). Additional consequences of climate change include increased ocean stratification, decreased sea-ice extent, altered patterns of ocean circulation, and decreased ocean oxygen levels (Doney et al. 2012). Further, ocean acidity has increased by 26 percent since the beginning of the industrial era (IPCC 2014) and this rise has been linked to climate change. Climate change is also expected to increase the frequency of extreme weather and climate events including, but not limited to, cyclones, heat waves, and droughts. (IPCC 2014) Climate change has the potential to impact species abundance, geographic distribution, migration patterns, timing of seasonal activities (IPCC 2014), and species viability into the future. Though predicting the precise consequences of climate change on highly mobile marine species, such as many of those considered in this Opinion, is difficult (Simmonds and Isaac 2007), recent research has indicated a range of consequences already occurring.

Marine species ranges are expected to shift as they align their distributions to match their physiological tolerances under changing environmental conditions (Doney et al. 2012). Hazen et al. (2012) examined top predator distribution and diversity in the Pacific Ocean in light of rising sea surface temperatures using a database of electronic tags and output from a global climate model. He predicted up to a 35 percent change in core habitat area for some key marine predators in the Pacific Ocean, with some species predicted to experience gains in available core habitat and some predicted to experience losses. Notably, leatherback sea turtles were predicted to gain core habitat area, whereas loggerhead sea turtles and blue whales were predicted to experience losses in available core habitat. McMahon and Hays (2006a) predicted increased ocean temperatures would expand the distribution of leatherback sea turtles into more northern latitudes. The authors noted this is already occurring in the Atlantic Ocean. MacLeod (2009) estimated, based upon expected shifts in water temperature, 88 percent of cetaceans would be affected by climate change, with 47 percent likely to be negatively affected.

Similarly, climate-mediated changes in important prey species populations are likely to affect predator populations. For example, blue whales, as predators that specialize in eating krill, are likely to change their distribution in response to changes in the distribution of krill (Clapham et al. 1999; Payne et al. 1986; Payne et al. 1990). (Pecl and Jackson 2008) predicted climate change will likely result in squid that hatch out smaller and earlier, undergo faster growth over shorter life-spans, and mature younger at a smaller size. This could have significant negative consequences for species such as sperm whales, whose diets can be dominated by cephalopods. For ESA-listed species that undergo long migrations, if either prey availability or habitat suitability is disrupted by changing ocean temperature regimes, the timing of migration can change or negatively impact population sustainability (Simmonds and Eliott. 2009).

Changes in global climatic patterns are expected to have profound effects on coastlines worldwide, potentially having significant consequences for the species considered in this Opinion that are partially dependent on terrestrial habitat areas (i.e., sea turtles). For example, rising sea levels are projected to inundate some sea turtle nesting beaches (Caut et al. 2009b; Wilkinson and Souter 2008), change patterns of coastal erosion and sand accretion that are necessary to maintain those beaches, and increase the number of turtle nests destroyed by tropical storms and hurricanes (Wilkinson and Souter 2008). The loss of nesting beaches may have catastrophic effects on global sea turtle populations if they are unable to colonize new

beaches, or if new beaches do not provide the habitat attributes (e.g., sand depth, temperature regimes, refuge) necessary for egg survival. Additionally, increasing temperatures in sea turtle nests, as is expected with climate change, alters sex ratios, reduces incubation times (producing smaller hatchlings), and reduces nesting success due to exceeded thermal tolerances (Fuentes et al. 2009a; Fuentes et al. 2010; Fuentes et al. 2009b; Glen et al. 2003). All of these temperature related impacts have the potential to significantly impact sea turtle reproductive success and ultimately, long-term species viability. Poloczanska et al. (2009) noted that extant marine turtle species have survived past climatic shifts, including glacial periods and warm events, and therefore may have the ability to adapt to ongoing climate change (e.g., by finding new nesting beaches). However, the authors also suggested since the current rate of warming is very rapid, expected changes may outpace sea turtles' ability to adapt.

Previous warming events (e.g., El Niño, the 1977 through 1998 warm phase of the Pacific Decadal Oscillation) may illustrate the potential consequences of climate change. Off the U.S. west coast, past warming events have reduced nutrient input and primary productivity in the California Current, which also reduced productivity of zooplankton through upper-trophic level consumers (Doney et al. 2012; Sydeman et al. 2009; Veit et al. 1996). In the past, warming events have resulted in reduced food supplies for marine mammals along the U.S. west coast (Feldkamp et al. 1991; Hayward 2000; Le Boeuf and Crocker 2005). Some marine mammal distributions may have shifted northward in response to persistent prey occurrence in more northerly waters during El Niño events (Benson et al. 2002; Danil and Chivers 2005; Lusseau et al. 2004; Norman et al. 2004b; Shane 1994; Shane 1995). Low reproductive success and body condition in humpback whales may have resulted from the 1997/1998 El Niño (Cerchio et al. 2005).

In the NMFS's final rule to list 20 coral species as threatened (79 FR 53851), ocean warming and acidification, associated wtih climate change, were identified as two of the most important threats to the current or expected future extinction risk of reef building corals. Reef building organisms, such as the four coral species considered in this Opinion, are predicted to decrease the rate at which they deposit $CaCO_3$ in response to increased ocean acidity and warmer water temperatures (Raymundo et al. 2008). Further, the most severe coral bleaching events observed to date have typically been accompanied by ocean warming events such as the El Niño-Southern Oscillation (Glynn 2001). Bleaching episodes result in substantial loss of coral cover, and result in the loss of important habitat for associated reef fishes and other biota (e.g., sea turtles). Corals can typically withstand mild to moderate bleaching, but severe or prolonged bleaching events can lead to coral colony death (79 FR 53851). While the susceptibility to ocean warming and acidication associated with climate change is expected to vary by species and specific coral colony (based on latitude, depth, bathymetry, etc), climate change is expected to have major impacts on the coral species considered in this Opinion. Specifically, the final listing rule identified *Acropora globiceps* as having high vulnerability to the effects of ocean warming and moderate vulnerability to the effects of ocean acidification (79 FR 53851).

This is not an exhaustive review of all available literature regarding the potential impacts of climate change to the species considered in this Opinion. However, this review provides some examples of impacts that may occur. While it is difficult to accurately predict the consequences of climate change to the species considered in this Opinion, a range of consequences are

expected, ranging from beneficial to catastrophic. With the exception of corals, given a lack of available information within the context of the temporal scale of the action, specific climate change related impacts on the species evaluated in this Opinion are speculative, cannot be meaningfully assessed, and will not be considered further.

5.2 Coastal development and pollution

Coastal development intensifies use of coastal resources, resulting in potential impacts on water quality, marine habitat, and air quality. Development impacts coastal resources through point and nonpoint source pollution, increased sedimentation, concentrated recreational use, and intensive ship traffic using major port facilities. The Action Area coastline also includes coastal tourism development (e.g., hotels, resorts, restaurants, food industry, vacation homes) and the infrastructure supporting coastal development (e.g., retail businesses, marinas, fishing tackle stores, dive shops, fishing piers, recreational boating harbors, beaches, recreational fishing facilities). Coastal development is regulated by states and territories through the Coastal Zone Management Act and associated state and local programs.

Habitat degradation issues associated with development, such as poor water quality, invasive species, and disease, can alter ecosystems, limiting food availability and altering survival rates. For example, on Saipan, golf course, hotel and tourism-related development has severely impacted most of the historical sea turtle nesting areas on the western portion of the island and residential development threatens the eastern portion of the island. On Rota, turtle nesting beaches appear limited to undeveloped private land due to heavy recreational use and shoreside tourist developments. On Tinian, the majority of the nesting beaches are on military-leased land where no construction is presently expected.

Pollution of the marine environment is a pervasive problem throughout Guam and the inhabited Mariana Islands. Portions of the nearshore marine environment around Guam were severely degraded by impacts from intense combat during World War II (WWII); sunken ships still rest on the sea floor at several locations throughout Apra Harbor on Guam, as does metallic wreckage and other debris. Since WWII, the health of Guam's marine environment has been affected by the recreational, industrial and commercial operations associated with an increasing population. More recently, sedimentation (from illegal wildfires, improper development, and upland erosion), stormwater runoff and associated pollutants such as fertilizers and oil (from inadequate protections during coastal development and insufficient stormwater management practices and infrastructure) have been identified as the most serious threats to the health of Guam's nearshore marine environment. Increases in soil erosion can lead to sediment loading in coastal waters which directly impact reef building corals and indirectly impact sea turtles by altering habitat including coral reefs and sea grass beds.

The most common direct effect of sedimentation is deposition of sediment on coral surfaces as it settles out from the water column. Corals with certain morphologies (e.g., mounding) can passively reject settling sediments or corals can actively displace sediment by ciliary action or mucous production, both of which require energetic expenditures (Bak and Elgershuizen 1976; Dallmeyer et al. 1982; Lasker 1980; Stafford-Smith 1993; Stafford-Smith and Ormond 1992). Corals that are unsuccessful in removing sediment will be smothered and die (Golbuu et al. 2003; Riegl and Branch 1995; Rogers 1983). Sediment can also induce sublethal effects, such as reductions in tissue thickness (Flynn et al. 2006) and excess mucus production (Marszalek 1981).

In addition, suspended sediment can reduce the amount of light in the water column, making lessenergy available for coral photosynthesis and growth (Anthony and Hoegh Guldberg 2003; Bak 1978; Rogers 1979). While some corals may be more tolerant of short-term elevated levels of sedimentation, sediment stress and turbidity can induce bleaching (Philipp and Fabricius 2003; Rogers 1979). Finally, sediment impedes fertilization of spawned gametes (Gilmour 2002; Humphrey et al. 2008) and reduces larval settlement, as well as the survival of recruits and juveniles (Birrell et al. 2005; Fabricius et al. 2003).

The effects of chemical pollution on marine mammals are just starting to be understood (Aguilar Soto et al. 2008). Recently, the 5.5-year expedition of the *Odyssey* collected 955 biopsy samples from sperm whales around the world to provide a consistent baseline database of ocean contamination and to measure future effects (Ocean Alliance 2010). Chemical pollutants found in pesticides and other substances flow into the marine environment from human use on land and are absorbed into the bodies of marine mammals, accumulating in their blubber, internal organs, or are transferred to the young from mother's milk (Fair et al. 2010). Important factors that determine the levels of pesticides, heavy metals, and industrial pollutants that accumulate in marine mammals are gender (i.e., adult males have no way to transfer pesticides whereas females may pass pollutants to their calves through milk), habitat, and diet. Living closer to the source of pollutants and feeding on higher-level organisms increase the potential to accumulate toxins (Moon et al. 2010). The buildup of human-made persistent compounds in marine mammals not only increases their likelihood of contracting diseases or developing tumors but also compromises the function of their reproductive systems (Fair et al. 2010).

In addition to the effects of sediment-laden and polluted runoff, Guam's nearshore waters have been impacted by years of poorly treated wastewater effluent discharges around the island. In 1986, the U.S. Environmental Protection Agency issued permits under the National Pollutant Discharge Elimination System (NPDES) that allowed Guam Waterworks Authority to discharge wastewater effluent into the nearshore marine environment following primary treatment of wastewater. Primary treatment follows coarse screening and grit settlement, and removes only about 60 percent of the suspended solids in the wastewater by allowing the water to rest in settlement tanks that are used to remove material that floats or settles out (Mancl 1996). Following that, chlorination is normally employed to reduce pathogens. However, the NPDES permits expired in 1991 and were not reissued due to GWA's inability to meet the required standards (Guam 2003).

The lack of adequate wastewater treatment on Guam has contributed to nutrient inputs to nearshore waters. A 2010 assessment by GEPA determined that while most of the 24 assessed bays met water quality guidelines for recreational activities and harvesting, 11 of the bays were impaired. Over 700 swimming advisories due to bacterial counts in marine waters were issued in 2009, likely stemming from faulty septic tanks and non-compliance by treatment facilities with NPDES regulations for various parameters.

The overall health of Guam's coral reefs has declined over time; while it is difficult to assign the causes of this decline to local versus global causes, increased sedimentation and pollutant runoff are known stressors to reef-building corals. The average live coral cover in Guam's nearshore waters was approximately 50 percent in the 1960s, but dwindled to less than 25 percent by the 1990s, with only a few areas having over 50 percent live cover.

5.2.1 Light Pollution

The east end of Apra Harbor is highly developed and brightly illuminated at night. The existing lights from the commercial port are particularly bright and may be clearly visible to nesting turtles and hatchlings in the water, and on the beach, at Spanish Steps. Sea turtle hatchlings are strongly attracted to light (Witherington and Bjorndal 1991a), and use light wavelengths and shape patterns to find the ocean after emerging from the nest (Lohmann et al. 1997; Witherington 1992). Lighting from the commercial port in Apra Harbor, is clearly visible from Spanish Steps (Kevin Brindock, personal communication to Julie Rivers: 29 Oct. 2014); this light pollution may have the potential to impact green turtle reproductive success at the Spanish Steps.

5.3 Marine Debris

Debris can be introduced into the marine environment by its improper disposal, accidental loss, or natural disasters (Watters et al. 2010), and can include plastics, glass, derelict fishing gear, derelict vessels, or military expendable materials. Despite debris removal and outreach to heighten public awareness, marine debris in the environment has not been reduced (Academies 2008) and continues to accumulate in the ocean and along shorelines within the Action Area. Marine debris affects marine habitats and marine life worldwide, primarily by entangling or choking individuals that encounter it. Entanglement in marine debris can lead to injury, infection, reduced mobility, increased susceptibility to predation, decreased feeding ability, fitness consequences, and mortality for all listed species in the Action Area. Entanglement can also result in drowning for air breathing marine species including sea turtles, cetaceans, and pinnipeds. Marine debris ingestion can lead to intestinal blockage which can impact feeding ability and lead to death. Data on marine debris in the Action Area is largely lacking; therefore it is difficult to draw conclusions as the extent of the problem and its impacts on populations of listed species.

Sea turtles can mistake plastic bags for jellyfish, which are eaten by many turtle species in early life phases, and exclusively by leatherback turtles throughout their lives. One study found plastic in 37 percent of dead leatherbacks and determined that 9 percent of those deaths were a direct result of plastic ingestion (Mrosovsky et al. 2009). Other marine debris, including derelict fishing gear and cargo nets, can entangle and drown turtles of all life stages. In studying ingestion in 115 green and hawksbill sea turtles stranded in Queensland, Schuyler et al. (2012) found that the probability of debris ingestion was inversely correlated with size (curved carapace length), and when broken down into size classes, smaller pelagic turtles were significantly more likely to ingest debris than larger benthic feeding turtles. Parker et al. (2005) conducted a diet analysis of 52 loggerhead sea turtles collected as bycatch from 1990 to 1992 in the high seas drift gillnet fishery in the central north Pacific. The authors found that 34.6 percent of the individuals sampled had anthropogenic debris in their stomachs (e.g., plastic, Styrofoam, paper, rubber, etc). Similarly, a study of green sea turtles found that 61 percent of those observed stranded had ingested some form of marine debris, including rope or string, which may have originated from fishing gear (Bugoni et al. 2001). In 2008, two sperm whales stranded along the California coast, with an assortment of fishing related debris (e.g., net scraps, rope) and other plastics inside their stomachs (Jacobsen et al. 2010a). One whale was emaciated, and the other had a ruptured stomach. It was suspected that gastric impaction was the cause of both deaths. (Jacobsen et al. 2010a) speculated that the debris likely accumulated over many years, possibly in the North Pacific gyre that would carry derelict Asian fishing gear into eastern Pacific waters.

Plastic debris is a major concern because it degrades slowly and many plastics float. The floating debris is transported by currents throughout the oceans and has been discovered accumulating in oceanic gyres (Law et al. 2010). Additionally, plastic waste in the ocean chemically attracts hydrocarbon pollutants such as PCB and DDT. Fish, marine mammals and sea turtles can mistakenly consume these wastes containing elevated levels of toxins instead of their prey. In the North Pacific Subtropical Gyre it is estimated that the fishes in this area are ingesting 12,000 to 24,000 U.S. tons (10,886,216 to 21,772,433 kilograms [kg]) of plastic debris a year (Davison and Asch 2011).

In December 2013 a distressed juvenile hawksbill turtle was found entangled in marine debris in Garapan Lagoon, Saipan; a nylon rope tied in a loop had caught around the turtle's carapace and the turtle's body had apparently distorted around the restricting rope as it grew (Figure 16). The rope was removed and the turtle was released alive.

Figure 16: Juvenile hawksbill turtle entangled in marine debris recovered in Garapan Lagoon, Saipan, December 2013. Image: CNMI Department of Lands & Natural Resources.

Between October 2004 and September 2008, the American Samoa Department of Marine and Wildlife Resources (DMWR) necropsied four green turtles that stranded on Tutuila. Of those four, 2 had plastic and aluminum in their guts (Tagarino et al. 2008). However, because only a small percent of dead or dying sea turtles strand, little information is available to adequately quantify the impacts on sea turtles that may result from marine debris in the Action Area. Accumulated marine debris on sea turtle nesting beaches can also impede nesting success by altering nest excavation and through potential entrapment of hatchlings under debris that is inadvertently buried over them when the nesting female covers the clutch. The nesting beaches in the Spanish Steps area on Guam heavily impacted by accumulated marine debris and non-native plants.

5.4 Fisheries

Fisheries constitute an important and widespread use of the ocean resources throughout the Action Area. Fisheries can adversely affect fish populations, other species, and habitats. Direct effects of fisheries interactions include entanglement and entrapment which can lead to fitness consequences or mortality as a result of injury or drowning. Indirect effects include reduced prey availability and destruction of habitat. Potential impacts of fisheries include overfishing of targeted species and bycatch, both of which negatively affect fish stocks and other marine

resources. Bycatch is the capture of fish, marine mammals, sea turtles, marine birds, and other nontargeted species that occurs incidental to normal fishing operations. Use of mobile fishing gear, such as bottom trawls, disturbs the seafloor and reduces structural complexity. Indirect impacts of trawls include increased turbidity, alteration of surface sediment, removal of prey (leading to declines in predator abundance), removal of predators, ghost fishing (i.e., lost fishing gear continuing to ensnare fish and other marine animals), and generation of marine debris. Lost gill nets, purse seines, and long-lines may foul and disrupt bottom habitats and have the potential to entangle or be ingested by marine mammals.

Fisheries can have a profound influence on fish populations. In a study of retrospective data, Jackson et al. (2001) analyzed paleoecological records of marine sediments from 125,000 years ago to present, archaeological records from 10,000 years before the present, historical documents, and ecological records from scientific literature sources over the past century. Examining this longer-term data and information, Jackson et al. (2001) concluded that ecological extinction caused by overfishing precedes all other pervasive human disturbance of coastal ecosystems, including pollution and anthropogenic climatic change. Fisheries bycatch has been identified as a primary driver of population declines in several groups of marine species, including sharks, mammals, marine birds, and sea turtles (Wallace et al. 2010b).

Fisheries in the Action Area range from relatively small-scale, nearshore fisheries around Guam and the Commonwealth of the Northern Mariana Islands, to large-scale longline and purse seine fisheries prosecuted further offshore. Nearshore fisheries in the Action Area are based out of Guam or CNMI and operate from shore or out of small boats with little distinction among commercial, subsistence, or recreation trips (Council 2011), whereas the offshore fishery in the Action Area is primarily a commercial fishery, and includes high seas fishing activity from foreign vessels. Domestic fisheries based in Guam and the CNMI likely represent only a small percentage of the total fishing effort in the Action Area. International fleets, mainly from Asian nations, operate offshore and target pelagic species such as tunas, sharks and mahimahi.

Domestic fisheries based in Guam are divided into two basic categories: offshore and inshore fishing. Offshore fishing typically involves small boats (12–48 feet in length) that engage in one to two day trolling and bottom fishing trips to nearby banks, isles and pelagic areas. Inshore fishing is usually conducted without the use of a boat and consists mainly of casting (rod & reel fishing), throw-netting, and spearfishing. Data from the NOAA Pacific Islands Fishery Science Center indicates that the top fisheries in Guam in 2012, by weight, included skipjack tuna, mahimahi, wahoo, and marlins, as well as reef fish such as parrotfish and unicornfish.

The domestic commercial fishery of the CNMI is mainly a small boat troll fishery. Most fishing vessels are outboard-powered vessels less than 24 feet in length that make trolling trips of generally a day or less in duration. There are a few larger boats that have been used in recent years for bottom fishing around the islands north of Saipan in addition to trolling. Reef fishes make up a significant portion of the total commercial catch and are an important component of the local diet. While the vast majority of the domestic catch is consumed locally, there have been some intermittent exports to Guam, Hawaii, and Japan. Data from the NOAA Pacific Islands Fishery Science Center indicates that the top fisheries in Guam in 2012, by weight, included skipjack tuna, yellowfin tuna, mahimahi, wahoo, and reef fish.

Harvest from small-scale fisheries in the tropical Pacific in general is usually underestimated in official statistics due to the difficulty and costs of quantifying these very spatially diverse fisheries (Zeller et al. 2007). Zeller et al. (2005) re-estimated harvest of reef and bottom fishery catches in Guam and CNMI. The authors used estimated human consumption rates of the local population, and estimated values of exported/imported catches to estimate more representative catch numbers. The authors indicated a 2.5-fold underreporting of catches in Guam from 1965-2002, and a 2.2-fold underreporting of catches in CNMI from 1983 to 2002.

5.4.1 Bycatch

The term "bycatch" refers to any fisheries capture that is incidental to the intended or targeted species and can encompass all unwanted, unmanaged, or discarded animals captured. Bycatch in the Action Area occurs both as a result of nearshore fisheries based in Guam and CNMI as well as large-scale offshore fisheries operated by foreign fishing fleets. Bycatch is likely the most impactful problem presently facing cetaceans worldwide and may account for the deaths of more marine mammals than any other cause (Geijer and Read 2013; Hamer et al. 2010; Northridge 2008; Read 2008). Cetaceans are prone to bycatch in longline, trawl and purse seine fisheries, and large whales are prone to entanglement in trap or pot fisheries. Entanglement may also make whales more vulnerable to additional dangers, such as predation and ship strikes, by restricting agility and swimming speed. Wallace et al. (2010c) estimated that worldwide, 447,000 turtles are killed each year from bycatch in commercial fisheries. It is likely that the majority of individual sea turtles and marine mammals that are killed by commercial fishing gear are never detected, making it very difficult to accurately determine the number and frequency of mortalities.

Fisheries in the Action Area are likely result in the incidental capture and mortality of green, loggerhead, leatherback and hawksbill sea turtles, though data on sea turtle bycatch in the region are lacking. As greens and hawksbills nest on Guam and the CNMI, they are more likely to be encountered in nearshore waters are therefore more likely to be affected by nearshore fisheries based on Guam and the CNMI. Gill nets generally represent the most problematic fishery for sea turtles because the nets are often left untended, increasing the likelihood of drowning. Guam law prohibits drift gill nets and requires that staked gill nets be moved every six hours; these regulations would be expected to reduce the probability of mortality for any turtles incidentally captured. No such laws regarding gill nets exist in the CNMI that we are aware of. Sea turtles can also be hooked or entangled in hook-and-line fisheries, though the chance of survival is considered higher than if caught in a gill net. Leatherback sea turtles are known to have been occasionally captured offshore by Guam-based fishermen (Karen Frutchey, NMFS PIRO PRD, personal communication to Jordan Carduner, NMFS OPR, September 2014). In a study of stranded green turtles in Hawaii (those that are found on shore either injured, sick, or dead), the second and third most common known causes of stranding were fishing related. Hook-and-line fishing gear-induced trauma accounted for 7 percent, and gillnet fishing gear-induced trauma was responsible for 5 percent (Chaloupka et al. 2008b). However, most turtles that drown in fishing gear are likely never documented, making it very difficult to estimate the total number of turtles killed annually by nearshore fishing interactions, even in Hawaii where turtles are much better monitored and studied than in the Marianas.

We know very little about incidental fisheries interactions with cetaceans in the nearshore waters surrounding Guam and the CNMI. At the time this Opinion was written, the NMFS Pacific Islands Regional Office had not received any reports of hookings or entanglements of cetaceans,

nor had they observed any sign of fisheries interactions with cetaceans during their surveys (Erin Oleson, NMFS PIRO PRD, personal communication to Jordan Carduner, NMFS OPR, October 2014). As described above, fishing fleets based out of Guam and CNMI are small in scale and there are very few longline vessels or purse seine vessels that operate out of regional ports; thus fisheries interactions with cetaceans would be less likely among these vessels than among the larger scale fishing fleets that operate offshore within the Action Area. While we suspect that interactions with cetaceans likely occur among the offshore fisheries in the Action Area, data on these offshore fleets is scarce.

Bycatch of scalloped hammerhead sharks likely occurs in the Action Area though we are not aware of any data that is specific to the Action Area. Apra Harbor in Guam is considered an aggregation area for neonate and juvenile scalloped hammerheads, therefore incidental fisheries interactions with scalloped hammerheads near the harbor is a possibility; however we were not able to locate documentation of such bycatch. Guam law prohibits drift gill nets and requires that staked gill nets be moved every six hours; these regulations would be expected to reduce the probability of mortality for any sharks incidentally captured.

5.4.2 Directed Fisheries

The directed hunting of sea turtles in foraging areas and on nesting beaches as well as the harvesting of eggs from nesting beaches represent ongoing threats to sea turtles in the Action Area. Directed take through harvest of turtles and their nests continues on Guam and the other inhabited islands of the Mariana archipelago. Turtles were traditionally taken by residents of Guam for celebrations, and reports indicate that illegal harvesting still occurs. Poaching also occurs by immigrants, fishing crews, and tourists, especially those from areas where they are accustomed to eating turtles legally.

Between October 2013 and October 2014, the CNMI Department of Lands & Natural Resources reported two cases of attempted poaching of juvenile green sea turtles and one case of recovered juvenile green turtle remains that appeared consistent with poaching activity on Saipan, as well as the confiscation of five juvenile green turtle carapaces at Saipan International Airport. During the 2009 nesting season on Saipan, three out of what is thought to be a total of five nesting turtles were poached as were three nests. On Guam, DAWR has responded to 17 poachings of green sea turtles and 1 hawksbill since 1975. It is likely that the documented cases of poaching of adult sea turtles and sea turtle eggs represent just a fraction of the actual poaching cases that occur in the Action Area. Despite the evidence of continued poaching of adult sea turtles and sea turtle eggs, the available data on these activities is not adequate to allow for an accurate estimate of the impacts to listed sea turtle species in the Action Area.

Figure 17: Evidence of attempted poaching in the CNMI: A live juvenile green turtle found flipper-bound by a rubber strap, Saipan, 13 February 2014. Image courtesy of CNMI Department of Lands & Natural Resources.

Guam bans the possession, sale, or distribution of shark products, while the CNMI bans the landing of sharks at all ports within the archipelago. However, as described above, fisheries based in Guam and the CNMI are almost exclusively nearshore fisheries, and it is likely that offshore fisheries in the Action Area target sharks. Literature and technical reports describing fishing activity in the Action Area do not indicate that scalloped hammerhead sharks are directly targeted, though they are captured in shark fisheries that do not differentiate by species. Assessing harvest levels of scalloped hammerheads in the Action Area is difficult because many catch records do not differentiate among hammerhead species, or shark species in general (Miller 2014). For the nearshore fishery, the Western Pacific Fisheries Information Network (WPacFin) houses reported catch data from the fishery agencies of Guam (Division of Aquatic and Wildlife Resources; Bureau of Statistics and Plans) and CNMI (Division of Wildlife). However, reported shark catches for Guam and CNMI are aggregated into "Pelagic fishes" or "Sharks" categories for reporting purposes, making it difficult to differentiate scalloped hammerhead catch from these data. Similarly for the offshore environment, until 2011, the Western and Central Pacific Fisheries Commission (WCPFC) did not require the offshore fishery in the WCPFC Convention Area (inclusive of the Action Area) to report species specific information for many shark species, including hammerheads.

Observer data appears to be the most useful representation of species-specific catch rates in the offshore fishery of the Action Area (though it should be noted that these data are from observed fishing trips throughout the western and central Pacific Ocean and are not specific to the Action Area). Observer data from 1994 to 2009 indicates that hammerhead shark catch accounted for 0.2 percent of the total observed catch, by weight for longline fisheries (Programme 2010). Observer data from the purse seine fishery during the same time period indicated even lower shark catch rates: excluding catches of silky, whale, and oceanic whitetip sharks which were reported separately, catches of "Other sharks and rays" (inclusive of scalloped hammerhead sharks) represented only 0.01 percent of the total catch by weight of observed purse seine catches .

Scalloped hammerheads, like many shark species, are targeted for their fins because they fetch a high commercial value in the Asian shark fin trade. It is thought that scalloped hammerheads,

and sharks in general, are likely under-reported in catch records as many records do not account for discards, or finned individuals (Miller 2014). Observer data from the longline fisheries of the Western and Central Pacific Ocean indicates that of the 104 scalloped hammerheads observed discarded from 1994-2009 (on over 3,000 observed trips), 72 percent of those discarded were finned. Also of note, an additional 157 hammerheads were observed discarded over this time, but were not identified to species. Approximately 61 percent of those discarded individuals were finned. It should be noted that only a very small percentage of fishing vessels in the offshore portions of the Action Area have observer coverage, and many of the vessels that are most likely to be engaged in shark finning activities are also least likely to carry observers onboard. Many countries and fisheries management entities have aimed to restrict shark finning, though the practice continues in many areas. Since 2008, the Western and Central Pacific Fisheries Commission has attempted to discourage shark finning by requiring that fishing vessels retain all parts of the shark excepting head, guts, and skins, to the point of first landing. Further, onboard fins cannot weigh more than 5 percent of the weight of sharks onboard, up to the first point of landing. Despite these restrictions, illegal fishing activity is well documented, particularly on the high seas where enforcement is difficult. Guam banned the possession, sale, offer for sale, take, purchase, barter, transport, export, import, trade, or distribution of shark fins (with exemptions for research and subsistence fishing) in 2011. Similarly, CNMI banned the possession, sale, offer for sale, trade, or distribution of shark fins (with exemptions for research and subsistence fishing) in 2011.

5.5 Whaling

Large whale population numbers in the Action Areas have historically been impacted by commercial exploitation, mainly in the form of whaling. During the height of global whaling, Guam was an important stopover for whaling ships in the Pacific Ocean. However, we are not aware of any directed hunting of whales that presently occurs in the Action Area. Prior to current prohibitions on whaling, most large whale species had been significantly depleted. Table 26 lists the reported catches of all whale species considered in this Opinion and the year in which the International Whaling Commission (IWC) issued a moratorium on harvest of that species.

Table 26. Reported Catch of Endangered Whales Considered in This Opinion, in the North Pacific Ocean

Species	Estimated total catch	Data years	Source	IWC moratorium
Blue whale	9,500 whales	1910 - 1965	(Ohsumi and Wada 1972)	1966
Fin whale	46,000 whales	1919 - 1945	(C. Allison, IWC, pers. comm.; cited in : (Carretta et al. 2014)	1976
Humpback whale	15,000 whales	1919 - 1987	(Tonnessen and Johnsen 1982); C. Allison, IWC unpubl. Data; cited in: (Carretta et al. 2014)	1966
Sei whale	61,500 whales	1947 - 1987	(C Allison, IWC, pers. comm.(Allison 2007)	1976
Sperm whale	258,000 whales	1947 - 1987	(C. Allison, IWC, pers. comm.; cited in: (Carretta et al. 2014)	1988

These whaling numbers represent minimum catches, as illegal or underreported catches are not included. For example, recently uncovered Union of Soviet Socialist Republics catch records indicate extensive illegal whaling activity between 1948 and 1979, with a harvest totalling 157,680 sperm whales in the North Pacific Ocean (Ivashchenko et al. 2014). Of these, only 132,505 were reported by the USSR to the Bureau of International Whaling Statistics. Additionally, despite the moratorium on large-scale commercial whaling, catch of some of these species still occurs in the Pacific Ocean whether it be under objection of the IWC, for aboriginal subsistence purposes, or under IWC special permit (Table 27). Although these fisheries operate outside of the Action Area, some of the whales killed in these fisheries are likely part of the same populations of whales occurring within the Action Area for this consultation.

Table 27. Catches taken in the Pacific Ocean by commercial, aboriginal, and scientific permit whaling since 1985. Note that the large majority of these catches were taken in the Northwest Pacific Ocean by either Japan or Russia (USSR prior to 1992). Data compiled from the International Whaling Commission website (iwc.int/home; accessed on January 24, 2015).

Year	Sperm whale	Gray whale	Sei whale

2013	1	127	100
Totals	444	3418	1089

Historically, commercial whaling caused all of the large whale species to decline to the point where they faced extinction risks high enough to list them as endangered species. Since the end of large-scale commercial whaling, the primary threat to these species has been eliminated. However, as described in greater detail in the *Status of Listed Resources* section of this Opinion, all whale species have not recovered from those historic declines. Scientists cannot determine if

those initial declines continue to influence current populations of most large whale species in the North Pacific. For example, the North Pacific right and Western North Pacific gray whales have not recovered from the effects of commercial whaling and continue to face very high risks of extinction because of their small population sizes and low population growth rates. In contrast, species such as the humpack whale has increased substantially from post-whaling population levels and appear to be recovering despite the impacts of ship strikes, interactions with fishing gear, and increased levels of ambient sound in the Pacific Ocean.

5.6 Ongoing U.S. Military Training and Testing Activities in the Action Area

This section summarizes the United States Pacific Fleet marine species monitoring under the MMPA LOA for at-sea training in the MIRC. This data was provided by the Navy in in the Comprehensive Exercise and Marine Species Monitoring Report for The U.S. Navy's Mariana Islands Range Complex. Department of the Navy, Commander, U.S. Pacific Fleet, Pearl Harbor, Hawaii. 31 October 2014. The majority of the training and testing activities the Navy conducts in the MITT Action Area and proposes to continue to conduct are similar, if not identical, to activities that have been occurring in the same locations for decades.

There were two individual MTEs that took place in the MIRC from 12 August 2010 to 15 July 2014. These MTEs are summarized in Table 28.

Table 28. Summary of Major Training Exercises in MIRC

Exercise Type	12 Aug 2010 – 15 Feb 2011	16 Feb 2011 – 15 Feb 2012	16 Feb 2012 – 15 Feb 2013	16 Feb 2013 – 15 Feb 2014	16 Feb 2014 – 15 Jul 2014	Reporting Period Total
Joint Multi-Strike Group Exercise	1	0	1	0	0	2
Total	1	0	1	0	0	2

There were 11 reported sightings of an estimated 47 marine mammals during MTEs in the MIRC from 12 August 2010 to 15 July 2014. These sightings are summarized in Table 29.

Table 29. Summary of Sightings during Major Training Exercises

Total	**39**	**0**	**8**	**0**	**0**	**47**

There were 4 total mitigation events where active sonar was powered down or shut down due to the sighting of marine mammals or sea turtles during MTEs from 12 August 2010 to 15 July 2014. These mitigation events are summarized in Table 30. All of these sightings were observed within 4,000 yards of the Navy unit; one was observed by an aircraft, and one was an acoustic detection. The Navy's unclassified annual exercise reports from 2010 through 2014 contain tables listing all marine mammals sighted during that reporting year and the range of the sighting.

Table 30.Summary of Mitigation Events During Major Training Exercises

Marine Animal Species	Range of Detection (Yards, <200, 200-500, 500-1,000, 1,000-2,000, >2,000)	Mitigation Measure Implemented	Un-required Mitigation (Yes/No)
12 August 2010 – 15 February 2011			
Generic	Acoustic detection	Sonar shut down	Yes
Whale	<200	Sonar shut down	No
Whale	200-500	Sonar shut down	No
Whale	>2,000	Sonar shut down/maneuvered	Yes
16 February 2011 – 15 February 2012			
No mitigation events during this period			
16 February 2012 – 15 February 2013			
No mitigation events during this period			
16 February 2013 – 15 February 2014			
No mitigation events during this period

No mitigation events during this period			

5.7 Other U.S. Military Activities in the MITT Action Area

The following sections describe other past and ongoing military activities in the MITT Action Area.

5.7.1 Guam and CNMI Military Relocation

NMFS PIRO issued a biological opinion on 25 August 2010 on the Department of Navy (DoN) Joint Guam Program Office's Guam and CNMI Military Relocation. The action included three primary components: 1) Relocating U.S. Marines from Okinawa to Guam; 2) Increasing and upgrading vessel berthing and related facilities in Apra Harbor to accommodate increased visits by aircraft carriers and their accompanying ships, collectively referred to as a Carrier Strike Group (CSG), as well as supporting increased visits by Amphibious Taskforce (ATF) ships; and 3) Stationing an Army Air and Missile Defense Task Force on Guam. The action included substantial new upland construction and infrastructure improvements to support the incoming Marine and Army forces. That construction was not expected to directly affect ESA-listed species under NMFS jurisdiction. However, it was determined that the work necessary to

increase and upgrade vessel berthing and related facilities in Apra Harbor was likely to affect ESA-listed marine species. The action was expected have indirect impacts on ESA-listed marine species through increased wastewater discharge and increased commercial and recreational vessel traffic that were expected to result from the proposed population increase on Guam. Thus, those actions were subject of the consultation. NMFS determined that an undeterminable number of green and hawksbill sea turtles were expected to be adversely affected by the action, primarily through behavioral modification. As of the drafting of this Opinion, the majority of in-water work (Inner Apra Harbor Wharf Repairs) associated with the action in the CNMI Military Relocation consultation has been completed.

In February 2012, the DoN initiated a Supplemental EIS to evaluate the environmental consequences of establishing a live-fire training range complex on Guam in support of the relocation of Marine Corps forces to the island. Scoping meetings for the Supplemental EIS were held in March 2012. On 27 April 2012, the U.S.-Japan Security Consultative Committee issued a joint statement announcing its decision to adjust the plans outlined in the May 2006 Realignment Roadmap document. In accordance with the adjustments (the "2012 Roadmap Adjustments"), the DoD adopted a new force posture in the Pacific which provided a substantially smaller Marine Corps relocation to Guam. As a result of the 2012 Roadmap Adjustments, the DoN expanded the scope of the Supplemental EIS to also evaluate the potential environmental consequences from construction and operation of a main cantonment area, including family housing, and associated infrastructure to support the relocation of a substantially reduced number of Marines than previously analyzed. The Supplemental EIS supplements the 2010 Final EIS for the Guam and CNMI Military Relocation. As of the drafting of this Opinion, the Final SEIS for this action had not yet been released to the public. United States Marine forces are not expected to arrive in Guam until facilities are built and operational. Under the currently proposed timeline, this will not occur until 2020 (DoN 2012).

5.7.2 X-Ray Wharf Improvements

The Department of the Navy is planning improvements to its X-Ray wharf facility at Naval Base Guam in Apra Harbor to accommodate two berths for the Navy's new class of supply ships. ESA Section 7 consultation was completed on 9 January 2014 by NMFS PIRO. The temporary displacement of green and hawksbill sea turtles from Apra Harbor was expected as a result of the wharf construction, but no take was anticipated as a result of the action.

5.7.3 Surveillance Towed Array Sensor System Low Frequency Active Sonar

The Navy operates up to four Surveillance Towed Array Sensor System Low Frequency Active Sonar systems for routine training, testing, and military operations. Based on current Navy national security and operational requirements, routine training, testing, and military operations using these sonar systems could occur in the in the Pacific Ocean (including the Action Area), Atlantic Ocean, Indian Ocean, and Mediterranean Sea. A summary of SURTASS LFA sonar missions and mitigation measure detections from 2002 to 2014 is presented in Table 31.

During the first two quarters of the current LOA reporting period (2014 to 2015), one mission was completed over one day, during which LFA sonar was transmitted for 1.25 hours. There were no visual, passive acoustic, or active acoustic detections of marine animals, shutdowns of the LFA sonar, or reports of dead or injured marine animals. The results of the mitigation monitoring and its effectiveness support the Navy's and NMFS' conclusions that the Navy's

protocols for the use of SURTASS LFA sonar provide an effective means of minimizing risk of injury to protected marine species.

Table 31. Summary of SURTASS LFA sonar missions and mitigation measure detections from 2002 through 2014.

Year [1]	Vessel	Mission Summary			Visual Detections	Passive Acoustic Detections	Active Acoustic HF/M3 Detections	HF/M3 Unavailable[2]	Mitigation Protocol Suspensions/ Delays
		Number	Days	LFA Sonar Hours

	USNS EFFECTIVE	3			0	0	0	0	0
	USNS IMPECCABLE	0			0	0	0	0	0
	USNS VICTORIOUS	1			0	0	1	0	1
	Totals	**162**	**545.64**	**1060.63**	**66**	**39**	**218**	**117**	**315**

[1] August to August
[2] LFA sonar suspended during HF/M3 non-availability
[3] Contact made when LFA sonar not transmitting
[4] Marine mammal passive contacts verified by HF/M3 sonar system
[5] One contact confirmed with HF/M3 sonar, second was a sea turtle
[6] Only one contact confirmed visually
[7] 1 visual sighting of a marine mammal after the mission ended and LFA sonar was non-operational
[8] 1 shut down due to loss of passive acoustics system
[9] Although 9 HF/M3 sonar detections occurred during the USNS ABLE's missions, SURTASS LFA sonar operators determined that 5 of the HF/M3 detections were not biological sonar returns. Thus, LFA sonar transmissions were not suspended or delayed as a result of the HF/M3 detections.

The post-operational incidental harassment estimates for SURTASS LFA sonar transmissions from August 2013 to August 2014 indicate no marine mammals from any stocks in the northwestern Pacific Ocean were exposed to received levels at or above 180 dB (with mitigation applied). Some marine mammals were estimated to have been exposed to SURTASS LFA sonar transmissions during this period at received levels between 120 and 180 dB during this period (Table 32). No marine mammal stranding events associated with the times and locations of SURTASS LFA sonar missions were reported during this period and no apparent avoidance reactions or acute effects to threatened or endangered species were observed in response to exposure from SURTASS LFA sonar transmissions.

Table 32. Estimated number of ESA-Listed species that may be exposed to U.S. Navy Surveillance Towed Array Sensor System Low Frequency Active Sonar at received levels between 120 and 180 dB from August 2013 through August 2014. Information compiled from SURTASS LFA sonar Annual Report (2013-2014 LOA).

Species	Number of marine mammals in stock	Number of animals exposed (received levels of 120 to 180dB)
Blue Whale	9,250	3
Fin Whale	9,250	15
Western North Pacific Gray Whale	121	2
Humpback Whale	1,107	20
Sperm Whale	102,112	74
North Pacific Right Whale	922	4

The available evidence does not indicate that the use of SURTASS LFA has any adverse population-level impact on the the species evaluated in this Opinion or has otherwise adversely impacted the environmental baseline in the Action Area.

5.7.4 Divert Activities and Exercises

The U.S. Air Force proposes improvements to an existing airfield and associated infrastructure in the Mariana Islands in support of expanding mission requirements in the western Pacific. In addition, divert capabilities for current, emerging, and future training activities are proposed. A Draft EIS analyzing environmental impacts associated with the divert activities and exercises was published in June 2012. As of the issuance of this Opinion, the Final EIS for this action had not yet been made available to the public.

5.7.5 Dredging, Filling and Explosive Clearing

Apra Harbor is a natural deep-water harbor, which has been heavily modified, particularly since World War II (Figure 18). Much of the harbor's current topography and bathymetry is manmade; the result of work begun by the U.S. Government in 1943. Extensive dredging and fill projects resulted in the creation of Inner Apra Harbor and its channel as well as the creation of Dry Dock Peninsula, Polaris Point, and the manmade northeastern and southeastern shorelines and the Glass Breakwater, which extends from Cabras Island, out and across Luminau Reef to provide increased protection for the harbor. Other impacts include the knolls (hard bottom sites that protrude at least 25 ft (7.6 m) above the harbor bottom) that were explosively cleared during WWII, because they were considered navigational hazards. Some of the shallower knolls have been used as anchorage sites since WWII, and some are still used by military and commercial vessels. The Guam and CNMI military relocation involves additional dredging in Inner Apra Harbor (Office 2010).

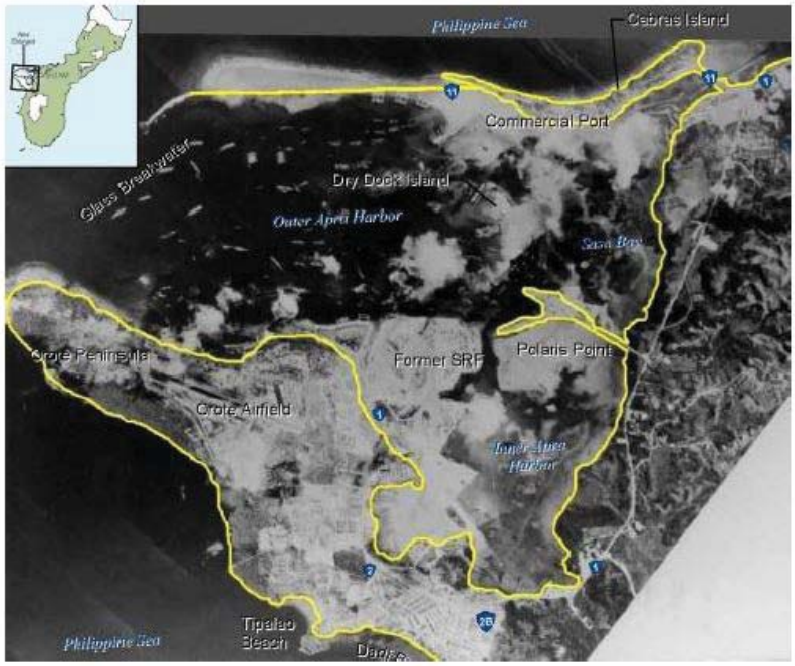

Figure 18. Apra Harbor July 1945. The yellow line indicates the approximate shoreline prior to the dredging and fill projects of the 1940s.

5.8 Commercial and Private Marine Mammal Watching

The 'whale watching' industry in the Action Area remains relatively small and is presently focused on dolphins rather than large whales. Although considered by many to be a non-consumptive use of marine mammals with economic, recreational, educational and scientific benefits, marine mammal watching is not without potential negative impacts. Whale watching has the potential to harass whales by altering feeding, breeding, and social behavior or even injure them if the vessel gets too close or strikes the whale. Another concern is that preferred habitats may be abandoned if disturbance levels are too high. Several studies have specifically examined the effects of whale watching on marine mammals, and investigators have observed a variety of short-term responses from animals, ranging from no apparent response to changes in vocalizations, duration of time spent at the surface, swimming speed, swimming angle or direction, respiration rate, dive time, feeding behavior, and social behavior (NMFS 2006b). Responses appear to be dependent on factors such as vessel proximity, speed, and direction, as well as the number of vessels in the vicinity (Au and Green 2000; Corkeron 1995; Erbe 2002b; Magalhaes et al. 2002; Richter et al. 2003; Scheidat et al. 2004; Watkins 1986; Williams et al. 2002a; Williams et al. 2002b). Foote et al. (2004) reported that southern resident killer whale call duration in the presence of whale watching boats increased by 10 to 15 percent between 1989 to 1992 and 2001 to 2003 and suggested this indicated compensation for a noisier environment. Disturbance by whale watch vessels has also been noted to cause newborn calves to separate briefly from their mothers' sides, which leads to greater energy expenditures by the calves (NMFS 2006b). Whale-watching vessels are also known to influence sperm whale behavior (Richter et al. 2006). Although numerous short-term behavioral responses to whale watching

vessels are documented, little information is available on whether long-term negative effects result from whale watching (NMFS 2006b). Christiansen et al. (2014) estimated the cumulative time minke whales spent with whale watching boats in Iceland to assess the biological significance of whale watching disturbances and found that, though some whales were repeatedly exposed to whale watching boats throughout the feeding season, the estimated cumulative time they spent with boats was very low. The authors suggested that the whale watching industry, in its current state, is likely not having any long-term negative effects on vital rates (Christiansen et al. (2014). To our knowledge, similar studies have not been conducted in Guam or CNMI.

5.9 Vessel Strike

Vessel strike is a significant concern for the recovery of listed whales and sea turtles. Evidence suggests that not all whales killed as a result of vessel strike are detected, particularly in offshore waters, and some detected carcasses are never recovered while those that are recovered may be in advanced stages of decomposition that preclude a definitive cause of death determination (Glass et al. 2010). Therefore, it is likely that the number of documented cetacean mortalities related to ship strikes is much lower than the actual number of mortalities associated with ship strikes. However, unlike other maritime entities, the Navy has a policy to report all ship strikes.

Ship strikes are a poorly-studied threat to sea turtles, but have the potential to be highly significant (Work et al. 2010b). All sea turtles must surface to breathe and several species are known to bask at the surface for long periods, including loggerhead sea turtles. Although sea turtles can move rapidly, they apparently are not adept at avoiding vessels that are moving at more than 4 km/hr; most vessels move far faster than this in open water (Hazel and Gyuris 2006; Hazel et al. 2007; Work et al. 2010b). Both live and dead sea turtles are often found with deep cuts and fractures indicative of collision with a boat hull or propeller (Hazel et al. 2007). Hazel et al. (2007) suggested that green sea turtles may use auditory cues to react to approaching vessels rather than visual cues, making them more susceptible to strike as vessel speed increases.

Portions of the Action Area are heavily traveled by commercial, recreational, and government marine vessels, with several commercial ports occurring in or near the Action Area. In the western Pacific Ocean, four waterways used by commercial vessels link Guam and the CNMI with major ports to both the east and west (Figure 19). Guam contains one commercial port located within Apra Harbor. The Port of Guam is the largest U.S. deepwater port in the Western Pacific and handles approximately 2 million tons (1,814,369,480 kilograms [kg]) of cargo a year (Port Authority of Guam 2011). The U.S. provides some 60 percent of Guam's imported goods, with the balance of Guam's trade coming from the Asian and Pacific markets of Japan, Taiwan, the Philippines, Hong Kong, and—to a lesser extent—Australia, New Zealand, and the islands of Micronesia (Port Authority of Guam 2011). Apra Harbor also provides economical transshipment services from the United States, Hawaii, and East Asia to the entire western Pacific. Most shipping lanes are located close to the coast but those that are trans-oceanic start and end to the northwest of Guam.

There are three ports within the CNMI. The Port of Rota, or Rota West Harbor, is located on the southwestern tip of the island and is classified as a very small port (World Port Source 2012a) that is mainly used for ferry boats. The Port of Tinian is described by the World Port Source as a

small port offering excellent shelter, which allows relatively large vessels to dock there. The Port of Saipan is the largest and most advanced of the three ports, but is nevertheless described as a small seaport with poor shelter by the World Port Source. A number of facilities and services are available at the Port of Saipan, which transferred over 338,000 tons of cargo in 2009 (Commonwealth Ports Authority 2005; Commonwealth Ports Authority 2010).

Major commercial shipping vessels use the shipping lanes for shipping goods between Hawaii, the continental U.S., and Asia. However, there are no direct routes between Guam and the U.S.; stops are made in Asia, and usually Japan or Korea, before continuing on to either Hawaii or the continental U.S. The total number of vessels transiting through the Port of Guam has steadily decreased from 2,924 in 1995 to 1,022 in 2008 (DoN 2010a). The Port Authority of Guam estimates 635 total vessel calls, not counting naval ships, in 2013. The decrease is most pronounced in the number of barges and fishing vessels that transit through the port; however, the number of container ships has increased from a low of 103 in 2003 to a high of 165 in 2008.

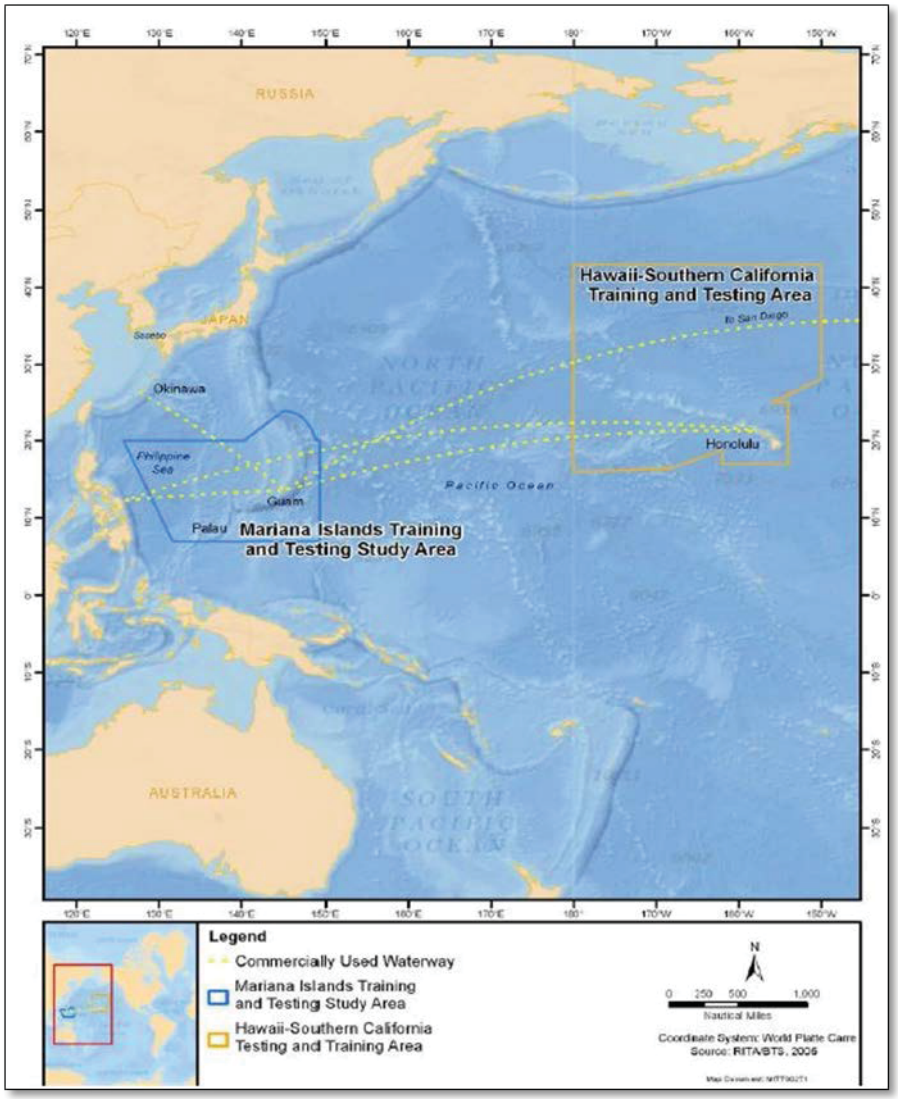

Figure 19: Shipping lanes in the Action Area

The magnitude of the risks commercial ship traffic pose to large whales in the proposed Action Area remains difficult to quantify or estimate. We struggle to estimate the number of whales that are killed or seriously injured in ship strikes on the U.S. Atlantic and Pacific coasts; information on ship strikes in Guam and the CNMI and in the offshore waters within the Action Area is virtually nonexistent. With the information available, we assume those interactions occur but we cannot estimate their significance to whale species.

As in the case of ship strikes to cetaceans, the information on ship strikes to sea turtles in the Action Area is lacking. Based on Hawaii data for the period of 1998 to 2007 (NMFS 2008), the estimated total number of green turtles killed annually by boat collisions in the Main Hawaiian Islands (MHI) was between 25 and 50. The number of hawksbills similarly killed was much lower; between 0.2 and 0.4 turtles annually. The nearshore densities of boats and turtles are

much lower around Guam and the CNMI than in Hawaiian nearshore waters, thus the number of green and hawksbill turtles killed annually by boat collisions around the Mariana Islands and surrounding waters is likely much lower. Although little information exists to quantify this impact, vessel collision has been implicated as the cause of three green turtle strandings in Apra Harbor between November 2002 and April 2008 (DAWR unpublished data).

5.10 Ocean Noise

A wide variety of anthropogenic and natural sources contribute to ocean noise throughout the world's oceans (Hatch and Wright 2007). Anthropogenic sources of noise that are most likely to contribute to increases in ocean noise are vessel noise from commercial shipping and general vessel traffic, oceanographic research, oil and gas exploration, underwater construction, and naval and other use of sound navigation and ranging.

Any potential for cumulative impact should be put into the context of recent changes to ambient sound levels in the world's oceans as a result of anthropogenic activities. However, there is a large and variable natural component to the ambient noise level as a result of events such as earthquakes, rainfall, waves breaking, and lightning hitting the ocean as well as biological noises such as those from snapping shrimp, other crustaceans, fishes, and the vocalizations of marine mammals (Crawford and Huang 1999; Patek 2002).

Andrew et al. (2002) compared ocean ambient sound from the 1960s to the 1990s from a receiver off the California coast. The data showed an increase in ambient noise of approximately 10 dB in the frequency ranges of 20–80 Hz and 200–300 Hz, and about 3 dB at 100 Hz over a 33-year period. Each 3 dB increase is noticeable to the human ear as a doubling in sound level. A possible explanation for the rise in ambient noise is the increase in shipping noise. There are approximately 11,000 supertankers worldwide, each operating approximately 300 days per year, each producing constant broadband noise at typical source levels of 198 dB (Hildebrand 2004). Generally the most energetic regularly operated sound sources are seismic airgun arrays from approximately 90 vessels with typically 12–48 individual guns per array, firing about every 10 seconds (Hildebrand 2004).

Seismic surveys are typically conducted by towing a sound source behind a research vessel, such as an airgun array that emits acoustic energy in timed intervals. The transmitted acoustic energy is reflected and received by an array of hydrophones. This acoustic information is processed to provide information about geological structure below the seafloor. The oil and gas industry conduct seismic surveys to search for new hydrocarbon deposits. In addition, research geologists conduct seismic surveys to study plate tectonics as well as other topics in marine geology. The underwater sound produced by seismic surveys could affect marine life, including ESA-listed marine species. All seismic surveys conducted by U.S. vessels are subject to the MMPA authorization process administered by the NMFS, as well as the NEPA process associated with issuing MMPA authorizations. Currently, there are several MMPA authorizations for seismic surveys near the Action Area, including one for the territorial waters of the CNMI.

Noise is of particular concern to marine mammals because many species use sound as a primary sense for navigating, finding prey, avoiding predators, and communicating with other individuals. As described in greater detail later in this Opinion, noise may cause marine

mammals to leave a habitat, impair their ability to communicate, or to cause stress. Noise can cause behavioral disturbances, mask other sounds including their own vocalizations, may result in injury and, in some cases, may result in behaviors that ultimately lead to death. The severity of these impacts can vary greatly between minor impacts that have no real cost to the animal, to more severe impacts that may have lasting consequences. A comprehensive discussion of the potential impacts of ocean noise on listed species is included in the *Effects of the Action* section of this Opinion.

Very little data is available on ocean noise and its impacts on listed species in the Action Area. The extent of commercial and recreational shipping in the Action Area, which directly influences the extent of ocean noise in a given area, is described above. The extent of noise-producing activities associated with U.S. Navy training and testing in the Action Area is described in detail in the *Effects of the Action* section of this Opinion.

5.10.1 Potential population-level impacts of anthropogenic noise

It is clear that impacts may result from increased levels of anthropogenic-induced background noise or high intensity, short-term anthropogenic sounds. The majority of impacts will likely be short-term behavioral responses, although more serious impacts are possible. Despite the potential for these impacts to affect individual animals, information is not currently available to determine the potential population level effect of anthropogenic sound levels in the marine environment (MMC 2007) on ESA-listed marine mammals and sea turtles. More information would be required including, but not limited to, empirical data on how sound impacts an individual's growth and vital rates, how these changes impact that individual's ability to reproduce successfully, and then the relative influence of that individual's reproductive success on the population being considered. As a result, the consequences of anthropogenic sound on threatened and endangered marine mammal and sea turtles at the population or species scale remain uncertain.

5.11 Invasive Species

Invasive species have been referred to as one of the top four threats to the world's oceans consistently ranked behind habitat degradation and alteration (Pughiuc 2010; Raaymakers 2003; Raaymakers and Hilliard 2002; Terdalkar et al. 2005; Wambiji et al. 2007). In most cases, habitat is directly affected by human alterations, as identified in the baseline section, such as hydromodification, mining, dredging, drilling, and construction. However, invasive species, facilitated by human commerce, have the ability to directly alter ecosystems upon which listed species rely.

Invasive species are a major threat to many ESA-listed species. For species listed by the USFWS, 26 percent were listed partially because of the impacts of invasive species and 7 percent were listed because invasive species were the major cause of listing (Anttila et al. 1998). Pimentel et al. (2004) found that roughly 40 percent of listed species are at risk of becoming endangered or extinct completely or in part due to invasive species, while Wilcove et al. (1998) found this to be 49 percent, with 27 percent of invertebrates, 37 percent of reptiles, 53 percent of fishes, and 57 percent of plants imperiled partly or wholly due to non-native invasions. In some regions of the world, up to 80 percent of species facing extinction are threatened by invasive species (Pimentel et al. 2004; Yan et al. 2002). Clavero and Garcia-Bertro (2005) found that

invasive species were a contributing cause to over half of the extinct species in the IUCN database; invasive species were the only cited cause in 20 percent of those cases. Richter et al. (1997) identified invasive species as one of three top threats to threatened and endangered freshwater species in the U.S. as a whole.

5.11.1 Diseases

The impacts of introduced pathogens in the aquatic environment has been poorly explored and we likely know very little about the true frequency and significance of pathogen invasions (Drake et al. 2001). Pathogens have adverse effects to invertebrate communities including reef-building corals. Various species of the genus *Vibrio*, known to cause cholera in humans, white pox and white plague type II diseases in corals have been identified in ports and ballast water of vessels (Aguirremacedo et al. 2008; Anguiano-Beltrán et al. 1998; Ben-Haim and Rosenberg 2002). Oyster species have sustained several outbreaks from invasive pathogens, including *Haplosporidium nelsoni* (the cause of MSX disease, which Chesapeake Bay eastern oysters have shown 75-92 percent mortality to) and *Perkinsus marinus* (the cause of Dermo disease) in California, eastern North America, and Europe (Andrews 1984; Burreson and Ford 2004; Burreson et al. 2000; Ford and Haskin 1982; Renault et al. 2000), *Bonamia ostreae* in Europe (Ciguarria and Elston 1997; Van Banning 1987), and in the northeastern US, respectively (Ford 1996).

5.11.2 Habitat Impacts

In general, species located higher within a food web (including most ESA-listed species under NMFS' jurisdiction) are more likely to become extinct as a result of an invasion; conversely, species that are more centrally or bottom-oriented within a food web are more likely to establish (Byrnes et al. 2007; Harvey and May 1997). Propagule pressure is generally the reason for this trend, as individuals lower in the food web tend to have higher fecundity and lower survival rates (r-selection). This unbalancing of food webs makes subsequent introductions more likely as resource utilization shifts, increasing resource availability, and exploitation success by non-native species (Barko and Smart 1981; Byrnes et al. 2007). Such shifts in the base of food webs fundamentally alters predator-prey dynamics up and across food chains (Moncheva and Kamburska 2002). The number of extinction events seems to be roughly correlated with the number of invasive establishments within an area (Harvey and May 1997).

Pathogens and species with toxic effects not only have direct effects to listed species, but also may affect habitat through ecosystem-mediated impacts. There are a number of non-native species that have the potential to either expel toxins at low levels, only becoming problematic for other members of the ecosystem if their population grows to very large sizes, resulting in very large amounts of toxins being released. In other cases, pathogens introduced to an environment may affect organisms that indirectly affect listed species.

Red tide dinoflagellates have been introduced via ballast water discharges and have the potential to undergo extreme seasonal population fluctuations. During bloom conditions, high levels of neurotoxins are released into local and regional surface water and air that can cause illness and death in fishes, sea turtles, marine mammals, and invertebrates (as well as their larvae) (Hallegraeff and Bolch 1992; Hallegraeff 1998; Hamer et al. 2001; Hamer et al. 2000; Lilly et al. 2002; McMinn et al. 1997). The brown alga, *Aureococcus anophagefferens*, causes brown tide

when it blooms, causing diebacks of eelgrass habitat due to blooms decreasing light availability and failure of scallops and mussels to recruit (Doblin et al. 2004).

The most commonly reported impact of non-native species in the coastal environment is competition for limited resources (Nyberg 2007). Molluscs, decapods, and aquatic plants tend to be especially capable invaders and have proven to be disruptive to food webs. The most common impacts are alteration of habitat and nutrient availability as well as altering species composition and diversity within an ecosystem (Strayer 2010). Crabs, polychaetes, and mussels can increase bioturbation and aerate the sediment (Nyberg 2007). Gastropods can alter the biogeochemical cycle through excretion of biogenic silicate in the faeces and pseudofaeces (Ragueneau et al. 2005). Molluscan invasions can also provide substrate for epibionts, shelter for benthic species, remove nutrients from the water, decrease turbidity and increase light penetration, remove sediments, and promote phytoplankton blooms by releasing nutrients from sediments (Bertness 1984; Gutierrez et al. 2003; Hecky et al. 2004). Invasives species may also prey upon ESA-listed species. For example, the crown-of-thorns sea star *Acanthaster planci* can significantly disrupt localized coral reef ecosystems by feeding on live coral (e.g., (Timmers et al. 2012)), including the ESA-listed coral considered in this Opinion. At the Tanguisson Reef, Guam, a population explosion of the sea star reduced coral cover to <1% of pre-disturbance levels in 1968-1969. However, the effect of the sea star can be relatively temporary. For example, at the Tanguisson Reef, coral species richness, cover, and composition reached or exceeded measurements of comparable reefs before the disturbance within 12 years (Colgan 1987).

Invasive plants can cause widespread habitat alteration, including native plant displacement, changes in benthic and pelagic animal communities, altered sediment deposition, altered sediment characteristics, and shifts in chemical processes such as nutrient cycling (Grout et al. 1997; Ruiz et al. 1999; Wigand et al. 1997). Introduced seaweeds alter habitat by colonizing previously unvegetated areas, while algae form extensive mats that exclude most native taxa, dramatically reducing habitat complexity and the ecosystem services provided by it (Wallentinus and Nyberg 2007). Invasive algae can alter native habitats through a variety of impacts, including trapping sediment, reducing the number of suspended particles that reach the benthos for benthic suspension and deposit feeders, reduce light availability, and adversely impact foraging for a variety of animals (Britton-Simmons 2004; Gribsholt and Kristensen 2002; Levi and Francour 2004; Sanchez et al. 2005). Invasive fishes can compose a large portion of fish taxa in at least some areas, including New Zealand where 53 percent of fish taxa are exotic, Puerto Rico where invasive fish are 91 percent of the total species, and Brazil where they are 13 percent of the total (Lövei 1997).

5.12 Scientific Research and Permits

Scientific research permits issued by the NMFS currently authorize studies of listed species in the Pacific Ocean which may occur in the Action Area. Table 33 identifies the cumulative number of takes for each listed marine mammal and sea turtle species in the Action Area authorized in scientific research permits. Cetacean takes include approach, biopsy, suction cup and implantable tagging, breath sampling, acoustic playbacks, and/or ultrasound. Sea turtle research involves approach, capture, handling, restraint, PIT, flipper, satellite, or sonic tagging, lavage, ultrasound, blood or tissue sampling, captive experiments, laproscopy, imaging, and/or antibiotic injections.

Table 33. Authorized takes of listed species in the Action Area under the ESA and/or MMPA.

Species	2005-2019 lethal take	2005-2014 sub-lethal take	2015-2019 sub-lethal take
Blue whale	0	9,935	10,035
Fin whale	0	11,619	15,521
Sei whale	0	8,102	6,408
Sperm whale	0	16,399	17,256
Green sea turtle	0	2,210	1,600
Hawksbill sea turtle	0	885	635
Leatherback sea turtle	0	0	0
Loggerhead sea turtle	0	0	0
Olive ridley sea turtle	0	0	0

Permit numbers: 1537, 1556, 14451, 15661, 15240[1], 15330, 16239[1], 17022[2], 17312[1], 731-1774[1], 18604

[1]This permit authorizes take throughout a large portion of the Pacific Ocean. Some of the take authorized is likely to occur within the Action Area.

[2]This permit authorizes take in waters surrounding various islands throughout the Pacific Ocean (e.g., Guam, Saipan, American Samoa, Johnson Atoll, Wake Island).

Several investigators have reported behavioral responses that suggest individual whales might experience stress responses to scientific research activities. Baker et al. (1983) described two responses of whales to vessels, including: (1) "horizontal avoidance" of vessels 2,000 to 4,000 meters away, characterized by faster swimming and fewer long dives; and (2) "vertical avoidance" of vessels from 0 to 2,000 meters away during which whales swam more slowly, but spent more time submerged. (Watkins 1981a) found that both fin and humpback whales appeared to react to vessel approach by increasing swim speed, exhibiting a startle reaction, and moving away from the vessel with strong fluke motions. Other researchers have noted changes in respiration, diving, swimming speed, social exchanges, and other behavior correlated with the number, speed, direction, and proximity of vessels. (Jahoda et al. 2003) studied the response of 25 fin whales in feeding areas in the Ligurian Sea to close approaches by inflatable vessels and to biopsy samples. They concluded close vessel approaches caused whales to stop feeding and swim away from the approaching vessel. The whales also tended to reduce the time they spent at surface and increase their blow rates, suggesting an increase in metabolic rates that might indicate a stress response to the approach. In their study, whales that had been disturbed while feeding remained disturbed for hours after the exposure ended. They recommended keeping vessels more than 200 meters from whales and having approaching vessels move at low speeds to reduce visible reactions.

5.13 Conclusion on the Impact of the Baseline on Listed Resources

Collectively, the stressors described above have had, and likely continue to have, lasting impacts on the ESA-listed species considered in this Opinion. Some of these stressors result in mortality or serious injury to individual animals (e.g., vessel strike, whaling), whereas others result in more indirect (e.g., a fishery that impacts prey availability) or non-lethal (e.g., whale watching, anthropogenic sound) impacts. Assessing the aggregate impacts of these stressors on the species considered in this Opinion is difficult and, to our knowledge, no such analysis exists. This becomes even more difficult considering that many of the species in this Opinion are wide ranging and subject to stressors in locations well beyond the Action Area.

We consider the best indicator of the aggregate impact of the *Environmental Baseline* on ESA-listed resources to be the status and trends of those species. As noted in Table 24, some of the species considered in this Opinion are seeing increases in population abundance, some are declining, and for some, the status remains unknown. Taken together, this indicates that the *Environmental Baseline* is impacting species in different ways. For the species that are increasing in population abundance, they are doing so despite the potential negative impacts of the *Environmental Baseline*. Therefore, while the *Environmental Baseline* described previously may slow their recovery, recovery is not being prevented. For the species that may be declining in abundance, it is possible that the suite of conditions described in the *Environmental Baseline* is preventing their recovery. However, it is also possible that their populations are at such low levels (e.g., due to historic commercial whaling) that even when the species' primary threats are removed, the species may not be able to achieve recovery. At small population sizes, they may experience phenomena such as demographic stochasticity, inbreeding depression, and Allee effects, among others, that cause their population size to become a threat in and of itself. A thorough review of the status and trends of each species is discussed thoroughly in the *Status of Listed Resources* section of this Opinion. Additionally, a brief discussion of the impacts of the Environmental Baseline on Guam's coral reefs in the MITT Action Area follows.

The overall health of Guam's reefs has declined over time, with impacts from global and local stressors contributing to a significant decline over recent decades. The average live coral cover was approximately 50 percent in the 1960s, but dwindled to less than 25 percent by the 1990s, with only a few areas having over 50 percent live cover. The health of Guam's coral reefs varies significantly. Reefs unaffected by sediment and nutrient loading, such as those in the northern part of the island and some coastal areas in the south, have healthy coral communities. Guam's reefs have been spared from large-scale bleaching events and coral diseases which are prevalent in many parts of the world. Big Blue Reef in Apra Harbor is considered one of the healthiest reefs in the harbor due to the reef's protection from water quality factors associated with Inner Apra Harbor and ship-induced sediment resuspension that impact other reef systems in the harbor. Reefs off Dry Dock Island, which was artificially created during WWII, are considered to also be among the healthiest reefs in the harbor, primarily due to protection from stressors. In contrast, the coral reef along Polaris Point, which was also constructed during WWII, is of marginal quality and has the greatest signs of stress, including high levels of total suspended solids likely derived from watershed discharge. Recent studies have identified evidence of anchor and/or anchor chain damage to coral in Apra Harbor, including the formation of a rubble field on the southern side of the floating dry dock. Movement of mooring chains on the southern side of the floating dry dock has produced a significant rubble field, although mooring chains on the northern (outer) side of the floating dry dock do not appear to have caused similar damage.

6 EFFECTS OF THE ACTION ON SPECIES AND CRITICAL HABITAT

In *Effects of the Action* sections of this Opinion, we present results of our assessment of the probable direct and indirect effects of federal actions that are the subject of a consultation as well as the direct and indirect effects of interrelated, and interdependent actions on threatened and endangered species and designated critical habitat. As we described in the *Approach to the Assessment* section of this Opinion, we organize our effects' analyses using a stressor identification - exposure – response – risk assessment framework; we conclude this section with

an *Integration and Synthesis of Effects* that integrates information we presented in the *Status of Listed Resources* and *Environmental Baseline* sections of this Opinion with the results of our exposure and response analyses to estimate the probable risks the action poses to endangered and threatened species.

The following sections present the U.S. Navy's predicted impacts on ESA-listed species for annual and non-annual, training and testing activities. We have assessed the Navy's methodology in NAEMO and determined that the modeling data is the best available to assess potential exposure and response to U.S. Navy stressors associated with training and testing. Potential take resulting from training and testing is totaled in our conclusions and in the incidental take statement of this opinion to provide the estimated, maximum annual assuming all activities assessed are conducted in the given year.

6.1 Stressors Associated with the Proposed Action

The potential stressors (risks) to ESA-listed species that we analyzed based on the training and testing activities the U.S. Navy proposes to conduct in the MITT Action Area are summarized in Table 34. A table of the determinations of effect for each species and each stressor is presented in Table 25.

What follows is a brief description of the stressors listed above. More information on each stressor is presented in the FEIS/OEIS, May 2015. Following the descriptions, we present the results of our exposure analyses, followed by the results of our response analyses.

Table 34. U.S. Navy Stressor Categories Analyzed in This Opinion

Stressor	Description of Stressor
Acoustic (sonar and other active acoustic sources, underwater explosives, weapons firing, launch and impact noise, aircraft noise, and vessel noise)	Effects on species from acoustic sources are dependent on a number of factors, including the type of sound received (non-impulse or impulse), the proximity of the animal to the sound source, and the duration, frequency, and intensity of the sound. Underwater sound propagation is highly dependent upon environmental characteristics such as bathymetry, bottom type, water depth, temperature, and salinity. The sound received at a particular location will be different than near the source due to the interaction of many factors, including propagation loss; how the sound is reflected, refracted, or scattered; the potential for reverberation; and interference due to multi-path propagation. Sonar and other active acoustic sources emit sound waves into the water to detect objects, safely navigate, and communicate. Most systems operate within specific frequencies (although some harmonic frequencies may be emitted at lower sound pressure levels). Most sonar use is associated with anti-submarine warfare (ASW) activities. Sonar use associated with mine warfare (MIW) would also contribute a notable portion of overall acoustic sound. Explosives used during training and testing activities include explosive ordnance, including bombs, missiles, and naval gun shells; torpedoes; demolition charges; and explosive sonobuoys. Depending on the activity, detonations would occur in the air, near the water's surface, or underwater (some torpedoes and sonobuoys). Demolition charges could occur near the surface, in the water column, or on the

Stressor	Description of Stressor
	seafloor. Most detonations would occur in waters greater than 200 ft. (61 m) in depth, and greater than 3 nm from shore, although MIW, demolition, and some testing detonations could occur in shallow water closer to shore. Detonations associated with ASW would typically occur in waters greater than 600 ft. (182.9 m) depth. Noise associated with weapons firing and the impact of non-explosive practice munitions (NEPM) could happen at any location within the Action Area but generally would occur at locations greater than 12 nm from shore for safety reasons. These training and testing events would occur in areas designated for anti-surface warfare and similar activities. The firing of a weapon may have several components of associated noise. Firing of guns could include sound generated by firing the gun (muzzle blast), vibration from the blast propagating through a ship's hull, and sonic booms generated by the projectile flying through the air. Missiles and targets would also produce noise during launch. In addition, the impact of NEPM at the water surface can introduce noise into the water. Fixed- and rotary-wing aircraft are used for a variety of training and testing activities throughout the Action Area, contributing both airborne and underwater sound to the ocean environment. Aircraft used in training and testing generally have reciprocating, turboprop, or jet engines. Motors, propellers, and rotors produce the most noise, with some noise contributed by aerodynamic turbulence. Aircraft sounds have more energy at lower frequencies. Takeoffs and landings occur at established airfields as well as on vessels at sea throughout the Action Area. Most aircraft noise would be produced around air fields in the range complex. Military activities involving aircraft generally are dispersed over large expanses of open ocean but can be highly concentrated in time and location. Vessels (including ships, small craft, and submarines) would produce low-frequency, broadband underwater sound. Overall, naval traffic is often a minor component of total vessel traffic (Mintz and Filadelfo 2011) (Mintz and Parker 2006). Commercial vessel traffic, which included cargo vessels, bulk carriers, passenger vessels, and oil tankers (all over 65 ft. [20 m] in length), was heaviest near and between the major shipping ports.
Energy **(electromagnetic devices)**	Electromagnetic devices are used in towed or unmanned MIW systems that mimic the electromagnetic signature of a vessel passing through the water. None of the devices include any type of electromagnetic "pulse." The devices work by emitting an electromagnetic field and mechanically generated underwater sound to simulate the presence of a ship. The sound and electromagnetic signature cause nearby mines to detonate. The static magnetic field generated by the electromagnetic devices is of relatively minute strength. Typically, the maximum magnetic field generated would be approximately 23 gauss (G). By comparison, magnetic field generated by a refrigerator magnet is between 150 and 200 G. The strength of an electromagnetic field decreases quickly with distance from the device. The magnetic field generated at a distance of 4 m from the source is comparable to the earth's magnetic field, which is approximately 0.5 G.

Stressor	Description of Stressor
Physical disturbance and strike **(vessels, in water devices, military expended materials)**	Physical disturbances, including direct strikes on marine animals, may occur in association with vessel movements, the use of in-water devices, and materials expended from vessels and aircraft. Vessels used as part of the Action include ships (e.g., aircraft carriers, surface combatants), support craft, small boats, and submarines, ranging in size from 5 to over 300 m. Large Navy ships generally operate at speeds in the range of 10–15 knots, and submarines generally operate at speeds in the range of 8–13 knots. Small craft (for purposes of this discussion, less than 40 ft. [12 m] in length), which are all support craft, have variable speeds. Locations of vessel use in the Action Area varies with the type of activity taking place, but greater activity would be expected near ports than in other areas of the Action Area. In-water devices as discussed in this analysis are unmanned vehicles, such as remotely operated vehicles, unmanned surface vehicles and unmanned undersea vehicles, and towed devices. These devices are self-propelled and unmanned or towed through the water from a variety of platforms, including helicopters and surface ships. In-water devices are generally smaller than most participating vessels ranging from several inches to about 15 m. These devices can operate anywhere from the water surface to the benthic zone. Certain devices do not have a realistic potential to strike marine animals because they either move slowly through the water column (e.g., most unmanned undersea vehicles) or are closely monitored by observers manning the towing platform (e.g., most towed devices). Military expended materials include: (1) all sizes of NEPM; (2) fragments from explosive munitions; and (3) expended materials other than munitions, such as sonobuoys, ship hulks, and expendable targets. Activities using NEPM (e.g., small-, medium-, and large-caliber gun ammunitions, missiles, rockets, bombs, torpedoes, and neutralizers), explosive munitions (generating munitions fragments), and materials other than munitions (e.g., flares, chaff, sonobuoys, decelerators/parachutes, aircraft stores and ballast, and targets) have the potential to contribute to the physical disturbance and strike stressor.

Stressor	Description of Stressor
Entanglement **(fiber optic cables and guidance wires, and decelerators/parachutes)**	The only type of cable expended during training and testing are fiber optic cables. Fiber optic cables are flexible, durable, and abrasion or chemical-resistant. The physical characteristics of the fiber optic material render the cable brittle and easily broken when kinked, twisted, or bent sharply (i.e., to a radius greater than 360 degrees). The fiber optic cable would be suspended within the water column during the activity, and then be expended to sink to the sea floor. The only types of wires expended during training and testing activities are guidance wires from heavy-weight torpedoes. Guidance wires are used to help the firing platform control and steer the torpedo. They trail behind the torpedo as it moves through the water or air. Finally, the guidance wire is released from both the firing platform and the torpedo then sinks to the ocean floor. The torpedo guidance wire is a single-strand, thin gauge, coated copper alloy. The tensile breaking strength of the wire is a maximum of 42 pounds (lb.) (19 kilograms [kg]) and can be broken by hand (Group 2005). The length of wire dispensed would generally be equal to the distance the torpedo travels to impact the target and any undispensed wire would be contained in the dispensers upon impact. Degradation rates for the wire may vary because of changing environmental conditions in seawater, but are likely to take between 12 and 45 months Aircraft-launched sonobuoys, lightweight torpedoes (such as the MK 46 and MK 54), illumination flares, and targets use nylon parachutes or decelerators ranging in size from 18 to 48 in. (46 to 122 cm) in diameter. Decelerators are made of cloth and nylon, and many have weights attached to the lines for rapid sinking. At water impact, the decelerator assembly is expended, and it sinks away from the unit. The decelerator assembly may remain at the surface for 5–15 seconds before the decelerator and its housing sink to the seafloor, where it becomes flattened (Group 2005). Some decelerators are weighted with metal clips that facilitate their descent to the seafloor. Once settled on the bottom the canopy may temporarily billow if bottom currents are present.
Ingestion **(munitions and military expended materials other than munitions)**	The only munitions small enough for a marine mammal or sea turtles to ingest are small- and medium-caliber projectiles. These projectiles include all sizes up to and including 2.25 in. (57 mm) in diameter. Projectiles are composed of solid metal materials and would quickly move through the water column and settle on the seafloor where they are most likely to be encountered by bottom foraging animals. Sinking projectiles are unlikely to be encountered in the water column by marine mammals or sea turtles. Many different types of explosive munitions can result in fragments that are expended at sea during training and testing activities. Types of explosive munitions that can result in fragments include demolition charges, grenades, projectiles, missiles, and bombs. Fragments would result from fractures in the munitions casing and would vary in size depending on the size of the net explosive weight and munition type; however, typical sizes of fragments are unknown. These solid metal materials would quickly sink through the water column and settle to the seafloor. Military expended materials other than munitions include target fragments, chaff, and flares. At-sea targets are usually remotely operated airborne, surface, or subsurface traveling units, most of which, but not all, are designed to be recovered for re-use. However, if they are used during activities that utilize explosives then they may result in fragments. Expendable targets that may result in fragments would include air-launched decoys, surface targets (such as marine

Stressor	Description of Stressor
	markers, paraflares, cardboard boxes, and 10 ft. [3.05 m] diameter red balloons), and mine shapes. Most target fragments would sink quickly to the seafloor. Floating material, such as Styrofoam, may be lost from target boats and remain at the surface for some time Chaff consists of reflective, aluminum-coated glass fibers used to obscure ships and aircraft from radar-guided systems. Chaff, which is stored in canisters, is either dispensed from aircraft or fired into the air from the decks of surface ships when an attack is imminent. The glass fibers create a radar cloud that mask the position of the ship or aircraft. Chaff is composed of an aluminum alloy coating on glass fibers of silicon dioxide (Force 1997). Chaff is released or dispensed in cartridges or projectiles that contain millions of fibers. When deployed, a diffuse cloud of fibers is formed that is undetectable to the human eye. Chaff is a very light material, similar to fine human hair. It can remain suspended in air anywhere from 10 minutes to 10 hours and can travel considerable distances from its release point, depending on prevailing atmospheric conditions (Arfsten et al. 2002; Force 1997). Chaff cartridge plastic end caps and pistons would also be released into the marine environment, where they would persist for long periods and could be ingested by marine animals. Chaff end caps and pistons sink in saltwater (Spargo 2007). Flares are pyrotechnic devices used to defend against heat-seeking missiles, where the missile seeks out the heat signature from the flare rather than the aircraft's engines. Similar to chaff, flares are also dispensed from aircraft and fired from ships. The flare device consists of a cylindrical cartridge approximately 1.4 in. (3.6 cm) in diameter and 5.8 in. (14.7 cm) in length. Flares are designed to burn completely. The only material that would enter the water would be a small, round, plastic end cap (approximately 1.4 in. [3.6 cm] in diameter).
Secondary **(explosion byproducts, metals, chemicals, sedimentation, and transmission of marine mammal diseases and parasites)**	Secondary stressors associated with some training and testing activities could pose indirect impacts to ESA-listed marine species through habitat degradation or alteration or an effect on prey availability. Secondary stressors include (1) explosives, (2) explosion byproducts and unexploded ordnance, (3) metals, (4) chemicals, and (5) transmission of marine mammal diseases and parasites. In addition to directly impacting marine species, underwater explosions could impact other species in the food web, including prey species that ESA-listed marine species feed upon. The impacts of explosions would differ depending upon the type of prey species in the area of the detonation. Indirect impacts of explosives and unexploded ordnance to marine species via degradation of sediment or water quality is possible in the immediate vicinity of the ordnance. Explosion byproducts are not toxic to marine organisms at realistic exposure levels (Rosen and Lotufo 2010). Relatively low solubility of most explosives and their degradation products means that concentrations of these contaminants in the marine environment are relatively low and readily diluted. Metals are introduced into seawater and sediments as a result of training and testing activities involving ship hulks, targets, ordnance, munitions, and other military expended materials. Several training and testing activities introduce potentially harmful chemicals into

Stressor	Description of Stressor
	the marine environment; principally, flares and propellants for rockets, missiles, and torpedoes. Properly functioning flares missiles, rockets, and torpedoes combust most of their propellants, leaving benign or readily diluted soluble combustion byproducts (e.g., hydrogen cyanide). Operational failures allow propellants and their degradation products to be released into the marine environment. The greatest risk to marine species would be from perchlorate released from flares, missile, and rockets that operationally fail. Perchlorate is highly soluble in water, persistent, and impacts metabolic processes in many plants and animals. The U.S. Navy deploys trained Atlantic bottlenose dolphins (Tursiops truncatus) and California sea lions (Zalophus californianus) for integrated training involving two primary mission areas; to find objects such as inert mine shapes, and to detect swimmers or other intruders around Navy facilities such as piers. When deployed, the animals are part of what the Navy refers to as Marine Mammal Systems. These Marine Mammal Systems include one or more motorized small boats, several crew members, and a trained marine mammal. Based on the standard operating procedures with which these systems are deployed, it is not reasonably foreseeable that use of these marine mammals systems would result in the transmission of disease or parasites to ESA-listed cetacea in the Action Area.

6.2 Risk Assessment Framework – Marine Mammals

The following is a summary of available information used to develop the Navy's risk assessment criteria for acoustic stressors. We subsequently reviewed and adopted the criteria for this risk analysis.

6.2.1 Direct Injury of Marine Mammals From Acoustic Stressors

The potential for direct injury of marine mammals has been inferred from terrestrial mammal experiments and from post-mortem examination of marine mammals believed to have been exposed to underwater explosions (Ketten et al. 1993; Richmond et al. 1973; Yelverton et al. 1973). Additionally, non-injurious effects on marine mammals (e.g., TTS) are extrapolated to injurious effects (e.g., PTS) based on data from terrestrial mammals to derive the criteria serving as the potential for injury (Southall et al. 2007b). Actual effects on marine mammals may differ from terrestrial animals due to anatomical and physiological adaptations to the marine environment, such as a reinforced trachea and flexible thoracic cavity (Ridgway and Dailey 1972) that may decrease the risk of lung injury.

Potential non-auditory direct injury from non-impulsive sound sources, such as sonar, is unlikely due to relatively lower peak pressures and slower rise times than potentially injurious impulsive sources such as explosives. Non-impulsive sources also lack the strong shock waves associated with explosions. Therefore, primary blast injury and barotrauma (i.e., injuries caused by large pressure changes; discussed below) would not occur from exposure to non-impulsive sources such as sonar. Further, though there have been marine mammal strandings associated with use of sonar, as Ketten (2012) has recently summarized, "to date, there has been no demonstrable evidence of acute, traumatic, disruptive, or profound auditory damage in any marine mammal as the result [of] anthropogenic noise exposures, including sonar." The theories of sonar induced acoustic resonance and sonar induced bubble formation are discussed below. These phenomena,

if they were to occur, would require the co-occurrence of a precise set of circumstances that are unlikely to occur.

6.2.2 Primary Blast Injury and Barotrauma

The greatest potential for direct, non-auditory tissue effects is primary blast injury and barotrauma after exposure to high amplitude impulsive sources, such as explosions. Primary blast injuries result from the initial compression of a body exposed to a blast wave. Primary blast injury is usually limited to gas-containing structures (e.g., lung and gut) and the auditory system (Craig Jr. 2001a; Craig Jr. and Hearn 1998). Barotrauma refers to injuries caused when large pressure changes occur across tissue interfaces, normally at the boundaries of air-filled tissues such as the lungs. Primary blast injury to the respiratory system may be fatal depending upon the severity of the trauma. Rupture of the lung may introduce air into the vascular system, producing air emboli that can restrict oxygen delivery to the brain or heart. Though often secondary in life-threatening severity to pulmonary blast trauma, the gastrointestinal tract can also suffer contusions and lacerations from blast exposure, particularly in air-containing regions of the tract. Although hemorrhage of solid organs (e.g., liver, spleen, and kidney) from blast exposure is possible, rupture of these organs is rarely encountered.

The only known occurrence of mortality or injury to a marine mammal due to U.S. Navy training or testing involving impulsive sources occurred in March 2011 at the Silver Strand Training Complex. Prior to this incident, this area had been used for underwater demolitions training for at least three decades without incident. On this occasion, however, a group of long-beaked common dolphins entered the mitigation zone surrounding an area where a time-delayed firing device had been initiated on an explosive with a net explosive weight of 8.76 lb (3.97 kg) placed at a depth of 48 ft. (14.6 m). Approximately 1 minute after detonation, three animals were observed dead at the surface; a fourth animal was discovered 3 days later stranded dead 42 nm to the north of the detonation. Upon necropsy, all four animals were found to have sustained typical mammalian primary blast injuries (Danil and St. Leger 2011). See the MITT Final EIS/OEIS for more information on the topic of stranding. Since this incident, the Navy, in consultation with NMFS, developed additional mitigation measures to minimize the potential for similar incidents in the future.

6.2.3 Auditory Trauma

Relatively little is known about auditory system trauma in marine mammals resulting from a known sound exposure. A single study spatially and temporally correlated the occurrence of auditory system trauma in humpback whales with the detonation of a 5,000 kg (11,023 lb.) explosive (Ketten et al. 1993). The exact magnitude of the exposure in this study cannot be determined, but it is likely the trauma was caused by the shock wave produced by the explosion. There are no known occurrences of direct auditory trauma in marine mammals exposed to tactical sonar or other non-impulsive sound sources (Ketten 2012). The potential for auditory trauma in marine mammals exposed to impulsive sources (e.g., explosions) is inferred from tests of submerged terrestrial mammals exposed to underwater explosions (Ketten et al. 1993; Richmond et al. 1973; Yelverton et al. 1973).

6.2.4 Acoustic Resonance

Acoustic resonance has been proposed as a hypothesis suggesting that acoustically induced vibrations (sound) from sonar or sources with similar operating characteristics could be damaging tissues of marine mammals. In 2002, NMFS convened a panel of government and private scientists to investigate the issue (NMFS 2002). They modeled and evaluated the likelihood that Navy mid-frequency sonar caused resonance effects in beaked whales that eventually led to their stranding in the Bahamas (DoN 2015). The conclusions of that group were that resonance in air-filled structures was not likely to have caused the stranding (NMFS 2002). The frequencies at which resonance was predicted to occur were below the frequencies utilized by the mid-frequency sonar systems associated with the Bahamas event. Furthermore, air cavity vibrations, even at resonant frequencies, were not considered to be of sufficient amplitude to cause tissue damage, even under the worst-case scenario in which air volumes would be undamped by surrounding tissues and the amplitude of the resonant response would be maximal. These same conclusions would apply to other training activities involving acoustic sources. Therefore, we conclude that acoustic resonance is not likely under realistic conditions during training and testing activities and this type of impact is not considered further in this analysis.

6.2.5 Bubble Formation (Acoustically Induced)

A suggested cause of injury to marine mammals is rectified diffusion (Crum and Mao 1996), the process of increasing the size of a bubble by exposing it to a sound field. The process is dependent upon a number of factors including the sound pressure level and duration. Under this hypothesis, one of three things could happen: (1) bubbles grow to the extent that tissue hemorrhage (injury) occurs, (2) bubbles develop to the extent an immune response is triggered or nervous tissue is subjected to enough localized pressure that pain or dysfunction occurs (a stress response without injury), or (3) the bubbles are cleared by the lung without negative consequence to the animal. The probability of rectified diffusion, or any other indirect tissue effect, will necessarily be based upon what is known about the specific process involved. Rectified diffusion is more likely if the environment in which the ensonified bubbles exist is supersaturated with gas. Repetitive diving by marine mammals can cause the blood and some tissues to accumulate gas to a greater degree than is supported by the surrounding environmental pressure (Ridgway and Howard 1979). The dive patterns of some marine mammals (e.g., beaked whales) are theoretically predicted to induce greater supersaturation (Houser 2010; Houser et al. 2001b). If rectified diffusion were possible in marine mammals exposed to high-level sound, conditions of tissue supersaturation could theoretically speed the rate of bubble growth and increase the size of the bubbles. Subsequent effects due to tissue trauma and emboli would presumably mirror those observed in humans suffering from decompression sickness. It is unlikely the short duration of sonar or explosion sounds would be long enough to drive bubble growth to any substantial size, if such a phenomenon occurs.

An alternative but related hypothesis has also been suggested: stable microbubbles could be destabilized by high-level sound exposures such that bubble growth then occurs through static diffusion of gas out of the tissues. In such a scenario, the marine mammal would need to be in a gas-supersaturated state for enough time for bubbles to become a problematic size. Recent research with *ex vivo* supersaturated bovine tissues suggested that for a 37 kHz signal, a sound exposure of approximately 215 dB re 1 µPa would be required before microbubbles became

destabilized and grew (Crum et al. 2005). Assuming spherical spreading loss and a nominal sonar source level of 235 dB re 1 µPa at 1 m, a whale would need to be within 10 m (33 ft.) of the sonar dome to be exposed to such sound levels. Furthermore, tissues in the study were supersaturated by exposing them to pressures of 400 to 700 kilopascals for hours and then releasing them to ambient pressures. Assuming the equilibration of gases with the tissues occurred when the tissues were exposed to the high pressures, levels of supersaturation in the tissues could have been as high as 400 to 700 percent. These levels of tissue supersaturation are substantially higher than model predictions for marine mammals (Houser et al. 2001a; Saunders et al. 2008). It is improbable this mechanism is responsible for stranding events or traumas associated with beaked whale strandings. Both the degree of supersaturation and exposure levels observed to cause microbubble destabilization are unlikely to occur.

There is considerable disagreement among scientists as to the likelihood of this phenomenon (Evans and Miller 2004; Piantadosi and Thalmann 2004). Although it has been argued that traumas from recent beaked whale strandings are consistent with gas emboli and bubble-induced tissue separations (Fernandez et al. 2005a; Jepson et al. 2003), bubble formation as the cause of the traumas has not been verified. The presence of bubbles postmortem, particularly after decompression, is not necessarily indicative of bubble pathology (Bernaldo de Quiros et al. 2012; Dennison et al. 2011; Moore et al. 2009). Prior experimental work has also demonstrated the post-mortem presence of bubbles following decompression in laboratory animals can occur as a result of invasive investigative procedures (Stock et al. 1980).

6.2.6 Nitrogen Decompression

Although not a direct injury, variations in marine mammal diving behavior or avoidance responses could possibly result in nitrogen tissue supersaturation and nitrogen off-gassing. Nitrogen supersaturation and off-gassing levels could result in deleterious vascular and tissue bubble formation (Jepson et al. 2003) (Hooker et al. 2012; Saunders et al. 2008). Nitrogen off-gassing occurring in human divers is called decompression sickness. The mechanism for bubble formation from saturated tissues would be indirect and also different from rectified diffusion, but the effects would be similar. The potential process for this to occur is hypothetical and under debate in the scientific community (Hooker et al. 2012; Saunders et al. 2008). It is speculated if exposure to a startling sound elicits a rapid ascent to the surface, tissue gas saturation sufficient for the evolution of nitrogen bubbles might result (Fernandez et al. 2005a; Hooker et al. 2012; Jepson et al. 2003). In this scenario, the rate of ascent would need to be sufficiently rapid to compromise behavioral or physiological protections against nitrogen bubble formation.

Previous modeling suggests even unrealistically rapid rates of ascent from normal dive behaviors are unlikely to result in supersaturation to the extent bubble formation would be expected in beaked whales (Zimmer and Tyack 2007). Tyack et al. (2006) suggested emboli observed in animals exposed to mid-frequency active (MFA) sonar (Fernandez et al. 2005a; Jepson et al. 2003) could stem from a behavioral response that involves repeated dives, shallower than the depth at which lung collapse would occur. A bottlenose dolphin was trained to repetitively dive to to elevate nitrogen saturation to the point that asymptomatic nitrogen bubble formation was predicted to occur. However, inspection of the vascular system of the dolphin via ultrasound did not demonstrate the formation of any nitrogen gas bubbles (Houser 2010).

More recently, modeling has suggested that the long, deep dives performed regularly by beaked whales over a lifetime could result in the saturation of tissues (e.g., fat, bone lipid) to the point that they are supersaturated when the animals are at the surface (Hooker et al. 2009; Saunders et al. 2008). Proposed adaptations for prevention of bubble formation under conditions of persistent tissue saturation have been suggested (Fahlman et al. 2006; Hooker et al. 2009). Since bubble formation is facilitated by compromised blood flow, it has been suggested that rapid stranding may lead to bubble formation in animals with supersaturated tissues because of the stress of stranding and the cardiovascular collapse that can accompany it (Houser 2010).

A fat embolic syndrome was identified by Fernandez et al. (2005b) coincident with the identification of bubble emboli in stranded beaked whales. The fat embolic syndrome was the first pathology of this type identified in marine mammals, and was thought to possibly arise from the formation of bubbles in fat bodies, which subsequently resulted in the release of fat emboli into the blood stream. Recently, Dennison et al. (2011) reported on investigations of dolphins stranded in 2009 and 2010.Using ultrasound the authors identified gas bubbles in kidneys from 21 of 22 live-stranded dolphins and in the liver from two of 22. The authors postulated stranded animals are unable to recompress by diving, and thus may retain bubbles that are otherwise re-absorbed in animals that can continue to dive. The researchers concluded minor bubble formation can be tolerated since the majority of stranded dolphins released did not re-strand (Dennison et al. 2011). Recent modeling by Kvadsheim (2012) determined behavioral and physiological responses to sonar have the potential to result in bubble formation. However, the observed behavioral responses of cetaceans to sonar do not imply any significantly increased risk over what may otherwise occur normally in individual marine mammals. As a result, no marine mammals addressed in this analysis are given differential treatment due to the possibility for acoustically mediated bubble growth.

6.2.7 Hearing Loss

The most familiar effect of exposure to high intensity sound is hearing loss, meaning an increase in the hearing threshold. Both auditory injury and auditory fatigue may result in hearing loss. The meaning of the term “hearing loss” does not equate to “deafness.” Hearing loss is a noise-induced threshold shift, or simply a threshold shift. If high-intensity sound over stimulates tissues in the ear, causing a threshold shift, the impacted area of the ear (associated with and limited by the sound’s frequency band) no longer provides the same auditory impulses to the brain as before the exposure (Ketten 2012). The distinction between PTS and TTS is based on whether there is a complete recovery of a threshold shift following a sound exposure. If the threshold shift eventually returns to zero (the threshold returns to the pre-exposure value), the threshold shift is a TTS.

For TTS, full recovery of the hearing loss (to the pre-exposure threshold) has been determined from studies of marine mammals, and this recovery occurs within minutes to hours for the small amounts of TTS that have been experimentally induced (Finneran et al. 2005b; Finneran and Schlundt 2010; Nachtigall et al. 2004). The recovery time is related to the exposure duration, sound exposure level, and the magnitude of the threshold shift, with larger threshold shifts and longer exposure durations requiring longer recovery times (Finneran et al. 2005b; Finneran and Schlundt 2010; Mooney et al. 2009a; Mooney et al. 2009b). In some cases, threshold shifts as large as 50 dB (loss in sensitivity) have been temporary, although recovery sometimes required

as much as 30 days (Ketten 2012). If the threshold shift does not return to zero but leaves some finite amount of threshold shift, then that remaining threshold shift is a PTS. Again for clarity, PTS, as discussed in this document, is not the complete loss of hearing, but instead is the loss of hearing sensitivity over a particular range of frequency. Figure 20 shows one hypothetical threshold shift that completely recovers, a TTS, and one that does not completely recover, leaving some PTS. The actual amount of threshold shift depends on the amplitude, duration, frequency, temporal pattern of the sound exposure, and on the susceptibility of the individual animal.

Many are familiar with hearing protection devices (i.e., ear plugs) required in many occupational settings where pervasive noise could otherwise cause auditory fatigue and possibly result in hearing loss. The mechanisms responsible for auditory fatigue differ from auditory trauma and would primarily consist of metabolic fatigue and exhaustion of the hair cells and cochlear tissues. Note that the term "auditory fatigue" is often used to mean TTS; however, the Navy uses a more general meaning to differentiate fatigue mechanisms (e.g., metabolic exhaustion and distortion of tissues) from trauma mechanisms (e.g., physical destruction of cochlear tissues occurring at the time of exposure).

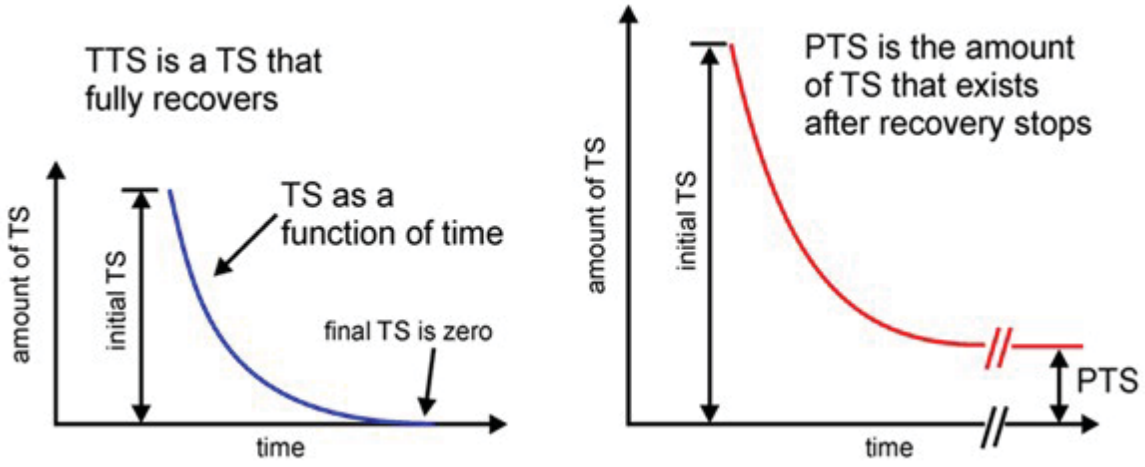

Figure 20. Two Hypothetical Threshold Shifts, Temporary and Permanent

Hearing loss, or auditory fatigue, in marine mammals has been studied by a number of investigators (Finneran et al. 2005b; Finneran and Schlundt 2010; Finneran et al. 2007; Finneran et al. 2000; Finneran et al. 2002; Lucke et al. 2009; Mooney et al. 2009a; Mooney et al. 2009b; Nachtigall et al. 2003; Schlundt et al. 2000). The studies of marine mammal auditory fatigue were all designed to determine relationships between TTS and exposure parameters such as level, duration, and frequency.

In these studies, hearing thresholds were measured in trained marine mammals before and after exposure to intense sounds. The difference between the pre-exposure and post-exposure thresholds indicated the amount of TTS. Species studied include the bottlenose dolphin, beluga, harbor porpoise, finless porpoise, California sea lion, harbor seal, and Northern elephant seal.

Some of the more important data obtained from these studies are onset-TTS levels—exposure levels sufficient to cause a measurable amount of TTS, often defined as 6 dB of TTS (Schlundt et al. 2000). These criteria for onset-TTS are very conservative, and it is not clear that this level of threshold shift would have a functional effect on the hearing of a marine mammal in the ocean.

The primary findings of the marine mammal TTS studies are:

- The growth and recovery of TTS shift are analogous to those in terrestrial mammals. This means that, as in terrestrial mammals, threshold shifts primarily depend on the amplitude, duration, frequency content, and temporal pattern of the sound exposure.

- The amount of TTS increases with exposure sound pressure level and the exposure duration.

- For continuous sounds, exposures of equal energy lead to approximately equal effects (Ward 1997). For intermittent sounds, less hearing loss occurs than from a continuous exposure with the same energy (some recovery will occur during the quiet period between exposures (Kryter et al. 1965; Ward 1997; (Kastelein et al. 2014a).

- Sound exposure level is correlated with the amount of TTS and is a good predictor for onset-TTS from single, continuous exposures with similar durations. This agrees with human TTS data presented by (Ward et al. 1958; Ward et al. 1959a; Ward et al. 1959b). However, for longer duration sounds beyond 16 to 32 seconds, the relationship between TTS and sound exposure level breaks down and duration becomes a more important contributor to TTS (Finneran and Schlundt 2010). Still, for a wide range of exposure durations, wound exposure level correlates reasonably well to TTS growth (Popov et al. 2014).

- The maximum TTS after tonal exposures occurs one-half to one octave above the exposure frequency (Finneran et al. 2007; Schlundt et al. 2000). TTS from tonal exposures can thus extend over a large (greater than one octave) frequency range.

- For bottlenose dolphins, sounds with frequencies above 10 kHz are more hazardous than those at lower frequencies (i.e., lower sound exposure levels required to affect hearing) (Finneran and Schlundt 2010) (Finneran and Schlundt 2013).

- The amount of observed TTS tends to decrease with increasing time following the exposure. The time required for complete recovery of hearing depends on the magnitude of the initial shift; for relatively small shifts recovery may be complete in a few minutes, while large shifts (e.g., 40 dB) may require several days for recovery.

- TTS can accumulate across multiple intermittent exposures, but the resulting TTS will be less than the TTS from a single, continuous exposure with the same sound exposure level. This means that predictions based on total, cumulative sound exposure level will overestimate the amount of TTS from intermittent exposures.

Although there have been no marine mammal studies designed to measure PTS, the potential for PTS in marine mammals can be estimated based on known similarities between the inner ears of marine and terrestrial mammals. Experiments with marine mammals have revealed their similarities with terrestrial mammals with respect to features such as TTS, age-related hearing loss (called Presbycusis), ototoxic drug-induced hearing loss, masking, and frequency selectivity. Therefore, in the absence of marine mammal PTS data, onset-PTS shift exposure levels may be estimated by assuming some upper limit of TTS that equates the onset of PTS, then using TTS relationships from marine and terrestrial mammals to determine the exposure levels capable of producing this amount of TTS.

Hearing loss resulting from auditory fatigue could effectively reduce the distance over which animals can communicate, detect biologically relevant sounds such as predators, and echolocate (for odontocetes). The costs to marine mammals with TTS, or even some degree of PTS have not been studied; however, a relationship between the duration, magnitude, and frequency range of hearing loss could have consequences to biologically important activities (e.g., intraspecific communication, foraging, and predator detection) that affect survivability and reproduction. However, the classification of modeled effects from acoustic stressors, such as TTS and PTS, are performed in a manner as to conservatively overestimate the impacts of those effects. Acoustic stressors are binned and all stressors within each bin are modeled as the loudest source, necessarily overestimating impacts within each bin. Therefore, the temporary duration of TTS may be on the shorter end of the range and last briefly. Even longer duration TTS is only expected to last hours or at most a few days. The brief amount of time marine mammals are expected to experience TTS is unlikely to significantly impair their ability to communicate, forage, or breed and will not have fitness level consequences at the individual or population level. Although PTS is a permanent shift in hearing, it is not the same as deafness and to our knowledge there are no published studies on the longterm effects of PTS on marine mammal fitness. Concievably, PTS could result in changes to individual's ability to communicate, breed, and forage but it is unclear if these impacts would significantly impact their fitness. Results from 2 years (2009 and 2010) of intensive monitoring by independent scientists and Navy observers in the SOCAL and Hawaii Range Complexes have recorded an estimated 161,894 marine mammals with no evidence of distress or unusual behavior observed during Navy activities. This supports that TTS and PTS are unlikely to significantly impair their ability to communicate, forage, or breed and will not have fitness level consequences at the individual or population level. For additional discussion on the effects of hearing loss on marine mammals see section 6.8.3.2.

6.2.8 Auditory Masking

Auditory masking occurs when a sound, or noise in general, limits the perception of another sound. As with hearing loss, auditory masking can effectively limit the distance over which a marine mammal can communicate, detect biologically relevant sounds, and echolocate (odontocetes). Unlike hearing loss, which likely results in a behavioral stress response,

behavioral changes resulting from auditory masking may not be coupled with a stress response. Another important distinction between masking and hearing loss is that masking only occurs in the presence of the sound stimulus, whereas hearing loss can persist after the stimulus is gone.

Critical ratios, a measure of the relative ability of an animal to extract signals from noise, have been determined for pinnipeds (Southall et al. 2000; Southall et al. 2003) and bottlenose dolphins (Johnson 1967) and detections of signals under varying masking conditions have been determined for active echolocation and passive listening tasks in odontocetes (Au and Pawloski 1989a; Au and Pawloski 1989b; Branstetter 2013; Erbe 2000; Johnson 1971). These studies provide baseline information from which the probability of masking can be estimated.

Clark et al. (2009) developed a methodology for estimating masking effects on communication signals for low frequency cetaceans, including calculating the cumulative impact of multiple noise sources. For example, their technique calculates that in Stellwagen Bank National Marine Sanctuary, when two commercial vessels pass through a North Atlantic right whale's (a baleen whale like blue, fin, sei, and humpback whales) optimal communication space (estimated as a sphere of water with a diameter of 20 km), that space is decreased by 84 percent. This methodology relies on empirical data on source levels of calls (which is unknown for many species), and requires many assumptions about ancient ambient noise conditions and simplifications of animal behavior. However, it is an important step in determining the impact of anthropogenic noise on animal communication. Subsequent research for the same species and location estimated that an average of 63 to 67 percent of North Atlantic right whale's communication space has been reduced by an increase in ambient noise levels, and that noise associated with transiting vessels is a major contributor to the increase in ambient noise (Hatch et al. 2012).

Vocal changes in response to anthropogenic noise can occur across sounds produced by marine mammals, such as whistling, echolocation click production, calling, and singing. Changes to vocal behavior and call structure may result from a need to compensate for an increase in background noise. In cetaceans, vocalization changes have been reported from exposure to anthropogenic noise sources such as sonar, vessel noise, and seismic surveying. Vocalizations may also change in response to variation in the natural acoustic environment (e.g., from variation in sea surface motion)(Dunlop et al. 2014).

In the presence of low frequency active sonar, humpback whales have been observed to increase the length of their songs (Fristrup et al. 2003; Miller et al. 2000), possibly due to the overlap in frequencies between the whale song and the low frequency active sonar. North Atlantic right whales have been observed to increase the frequency and amplitude (intensity) (Parks 2009) of their calls while reducing the rate of calling in areas of increased anthropogenic noise (Parks et al. 2007). In contrast, both sperm and pilot whales potentially ceased sound production during experimental sound exposure (Bowles et al. 1994), although it cannot be absolutely determined whether the inability to acoustically detect the animals was due to the cessation of sound production or the displacement of animals from the area.

Different vocal responses in marine mammals have been documented in the presence of seismic survey noise. An overall decrease in vocalization during active surveying has been noted in large

marine mammal groups (Potter et al. 2007). In contrast, blue whale feeding and social calls increased when seismic exploration was underway (Di Lorio and Clark 2010), indicative of a potentially compensatory response to the increased noise level. (Melcon et al. 2012) recently documented that blue whales decreased the proportion of time spent producing certain types of calls when simulated mid-frequency sonar was present. At present it is not known if these changes in vocal behavior corresponded to changes in foraging or any other behaviors. Controlled exposure experiments in 2007 and 2008 in the Bahamas recorded responses of false killer whales, short-finned pilot whales, and melon-headed whales to simulated MFA sonar (Deruiter et al. 2013a). The responses to exposures between species were variable. After hearing each MFA signal, false killer whales were found to "increase their whistle production rate and made more-MFA-like whistles" (Deruiter et al. 2013a). In contrast, melon-headed whales had "minor transient silencing" after each MFA signal, while pilot whales had no apparent response. Consistent with the findings of other previous research (see, for example, (Southall et al. 2007b)), Deruiter et al. (2013a) found the responses were variable by species and with the context of the sound exposure.

Evidence suggests that at least some marine mammals have the ability to acoustically identify predators. For example, harbor seals that reside in the coastal waters off British Columbia are frequently targeted by certain groups of killer whales, but not others. The seals discriminate between the calls of threatening and non-threatening killer whales (Deecke et al. 2002), a capability that should increase survivorship while reducing the energy required for attending to and responding to all killer whale calls. Auditory masking may prevent marine mammals from responding to the acoustic cues produced by their predators. The effects of auditory masking on the predator-prey relationship depends on the duration of the masking and the likelihood of encountering a predator during the time that predator cues are impeded.

6.2.9 Physiological Stress

Marine mammals naturally experience stressors within their environment and as part of their life histories. Changing weather and ocean conditions, exposure to diseases and naturally occurring toxins, lack of prey availability, social interactions with members of the same species, and interactions with predators all contribute to the stress a marine mammal experiences. In some cases, naturally occurring stressors can have profound impacts on marine mammals; for example, chronic stress, as observed in stranded animals with long-term debilitating conditions (e.g., disease), has been demonstrated to result in an increased size of the adrenal glands and an increase in the number of epinephrine-producing cells (Clark et al. 2006).

Anthropogenic activities have the potential to provide additional stressors above and beyond those that occur naturally. For example, various efforts have investigated the impact of vessels on marine mammals (both whale-watching and general vessel traffic noise) and demonstrated that impacts do occur (Bain 2002; Erbe 2002b; Noren et al. 2009; Pirotta et al. 2015; Williams and Ashe 2006; Williams and Noren 2009). In an analysis of energy costs to killer whales, Williams et al. (2009) suggested that whale-watching in the Johnstone Strait resulted in lost feeding opportunities due to vessel disturbance. Ayres et al. (2012) measured fecal hormones of southern resident killer whales in the Salish Sea to assess the lack of prey (salmon) and vessel traffic on species recovery. Ayres et al. (2012) suggested that the lack of prey overshadowed any population-level physiological impacts on southern resident killer whales from vessel traffic.

Marine mammals may exhibit a behavioral response or combinations of behavioral responses upon exposure to anthropogenic sounds. If a sound is detected by a marine mammal, a stress response (e.g., startle or annoyance) or a cueing response (based on a past stressful experience) can occur. Although preliminary because of the small numbers of samples collected, different types of sounds have been shown to produce variable stress responses in marine mammals. Belugas demonstrated no catecholamine (hormones released in situations of stress) response to the playback of oil drilling sounds (Thomas et al. 1990) but showed an increase in catecholamines following exposure to impulsive sounds produced from a seismic water gun (Romano et al. 2004). A bottlenose dolphin exposed to the same seismic water gun signals did not demonstrate a catecholamine response, but did demonstrate an elevation in aldosterone, a hormone that may be a significant indicator of stress in odontocetes (St. Aubin et al. 2001; St. Aubin and Geraci 1989). Increases in heart rate were observed in bottlenose dolphins to which conspecific calls were played, although no increase in heart rate was observed when tank noise was played back (Miksis et al. 2001). Collectively, these results suggest a variable response that depends on the characteristics of the received signal and prior experience with the received signal.

Other types of stressors include the presence of vessels, fishery interactions, acts of pursuit and capture, the act of stranding, and pollution. In contrast to the limited amount of work performed on stress responses resulting from sound exposure, a considerably larger body of work exists on stress responses associated with pursuit, capture, handling and stranding. A study compared pathological changes in organs/tissues of odontocetes stranded on beaches or captured in nets over a 40-year period (Cowan and Curry 2008). The type of changes observed indicate multisystemic harm caused in part by an overload of catecholamines into the system, as well as a restriction in blood supply capable of causing tissue damage or tissue death. This response to a stressor or stressors is thought be mediated by the over-activation of the animal's normal physiological adaptations to diving or escape. Pursuit, capture and short-term holding of belugas have been observed to result in decreased thyroid hormones (St. Aubin and Geraci 1988) and increases in epinephrine (St. Aubin and Dierauf 2001). In dolphins, the trend is more complicated with the duration of the handling time potentially contributing to the magnitude of the stress response (Ortiz and Worthy 2000; St. Aubin 2002; St. Aubin et al. 1996). Male grey seals subjected to capture and short-term restraint showed an increase in cortisol levels accompanied by an increase in testosterone (Lidgard et al. 2008). This result may be indicative of a compensatory response that enables the seal to maintain reproduction capability in spite of stress. Elephant seals demonstrate an acute cortisol response to handling, but do not demonstrate a chronic response; on the contrary, adult females demonstrate a reduction in the adrenocortical response following repetitive chemical immobilization (Engelhard et al. 2002). Similarly, no correlation between cortisol levels and heart/respiration rate changes were seen in harbor porpoises during handling for satellite tagging (Eskesen et al. 2009). Taken together, these studies illustrate the wide variations in the level of response that can occur when faced with these stressors.

Factors to consider when trying to predict a stress or cueing response include the mammal's life history stage and whether they are experienced with the stressor. Prior experience with a stressor

may be of particular importance as repeated experience with a stressor may dull the stress response via acclimation (St. Aubin and Dierauf 2001).

The sound characteristics that correlate with specific stress responses in marine mammals are poorly understood. Therefore, in practice and for the purposes of this Opinion, a stress response is assumed if a physical injury such as hearing loss or trauma is predicted; or if a significant behavioral response is predicted.

6.2.10 Behavioral Reactions

The response of a marine mammal to an anthropogenic sound will depend on the frequency, duration, temporal pattern and amplitude of the sound as well as the animal's prior experience with the sound and the context in which the sound is encountered (i.e., what the animal is doing at the time of the exposure). The distance from the sound source and whether it is perceived as approaching or moving away can affect the way an animal responds to a sound (Wartzok et al. 2003). For marine mammals, a review of responses to anthropogenic sound was first conducted by Richardson and others (Richardson et al. 1995c). More recent reviews (Ellison et al. 2012; Nowacek et al. 2007; Southall et al. 2009) (Southall et al. 2007b) address studies conducted since 1995 and focus on observations where the received sound level of the exposed marine mammal(s) was known or could be estimated.

Except for some vocalization changes that may be compensating for auditory masking, all behavioral reactions are assumed to occur due to a preceding stress or cueing response, however stress responses cannot be predicted directly due to a lack of scientific data (see preceding section). Responses can overlap; for example, an increased respiration rate is likely to be coupled with a flight response. Differential responses are expected among and within species since hearing ranges vary across species, the behavioral ecology of individual species is unlikely to completely overlap, and individuals of the same species may react differently to the same, or similar, stressor.

Southall et al. (2007a) synthesized data from many past behavioral studies and observations to determine the likelihood of behavioral reactions to specific sound levels exposures. While in general, the louder the sound source the more intense the behavioral response, it was clear that the proximity of a sound source and the animal's experience, motivation, and conditioning were also critical factors influencing the response (Southall et al. 2007b). After examining all of the available data, the authors felt that the derivation of thresholds for behavioral response based solely on exposure level was not supported because context of the animal at the time of sound exposure was an important factor in estimating response. Nonetheless, in some conditions consistent avoidance reactions were noted at higher sound levels dependent on the marine mammal species or group allowing conclusions to be drawn. Most low-frequency cetaceans (mysticetes) observed in studies usually avoided sound sources at levels of greater than or equal to 160 dB re 1 µPa. Published studies of mid-frequency cetaceans analyzed include sperm whales, belugas, bottlenose dolphins, and river dolphins. These groups showed no clear tendency, but for non-impulsive sounds, captive animals tolerated levels in excess of 170 dB re 1 µPa before showing behavioral reactions, such as avoidance, erratic swimming, and attacking the test apparatus. High-frequency cetaceans (observed from studies with harbor porpoises) exhibited changes in respiration and avoidance behavior at levels between 90 and 140 dB re 1 µPa, with

profound avoidance behavior noted for levels exceeding this. Phocid seals showed avoidance reactions at or below 190 dB re 1 µPa, thus seals may actually receive levels adequate to produce TTS before avoiding the source. Recent studies with beaked whales have shown them to be particularly sensitive to noise, with animals during 3 playbacks of sound breaking off foraging dives at levels below 142 dB re 1 µPa, although acoustic monitoring during actual sonar exercises revealed some beaked whales continuing to forage at levels up to 157 dB re 1 µPa (Tyack et al. 2011b). Passive acoustic monitoring of beaked whales, classified as Blainville's beaked whales and Cross-seamount type beaked whales, at Pacific Missile Range Facility, Kauai, Hawaii showed statistically significant differences in dive rates, diel occurrence patterns, and spatial distribution of dives after the initiation of a training event. However, for the beaked whale dives that continued to occur during MFAS activity, differences from normal dive profiles and click rates were not detected with estimated receive levels up to 137 dB re 1 uPa while the animals were at depth during their dives (Manzano-Roth et al. 2013b).

6.2.10.1 *Behavioral Reactions of Marine Mammals to Impulsive Sound Sources*

The following sections describe the behavioral reactions of marine mammals to impulsive sound sources such as underwater explosions.

6.2.10.1.1 Mysticetes

Baleen whales have shown a variety of responses to impulsive sound sources, including avoidance, reduced surface intervals, altered swimming behavior, and changes in vocalization rates (Richardson et al. 1995b; Southall et al. 2007d). While most bowhead whales did not show active avoidance until within 8 km of seismic vessels (Richardson et al. 1995a), some whales avoided vessels by more than 20 km at received levels as low as 120 dB re 1 µPa root mean square. Additionally, Malme et al. (1988) observed clear changes in diving and respiration patterns in bowheads at ranges up to 73 km from seismic vessels, with received levels as low as 125 dB re 1 µPa.

Gray whales migrating along the U.S. west coast showed avoidance responses to seismic vessels at 164 dB re 1 µPa (10 percent of animals showed avoidance response), and at 190 dB re 1 µPa (90 percent of animals showed avoidance response), with similar results for whales in the Bering Sea (Malme et al. 1986; Malme et al. 1988). In contrast, noise from seismic surveys was not found to impact Western North Pacific gray whale feeding behavior or exhalation rates off the coast of Russia (Gailey et al. 2007; Yazvenko et al. 2007).

Humpback whales showed avoidance behavior at ranges of 5 to 8 km from a seismic array during observational studies in western Australia (McCauley et al. 1998; Todd et al. 1996a) found no clear short-term behavioral responses by foraging humpbacks to explosions associated with construction operations in Newfoundland, but did see a trend of increased rates of net entanglement and a shift to a higher incidence of net entanglement closer to the noise source.

Seismic pulses at average received levels of 131 dB re 1 μPa^2-s caused blue whales to increase call production (Di Lorio and Clark 2010). McDonald et al. (1995) tracked a blue whale with seafloor seismometers and reported that it stopped vocalizing and changed its travel direction at a range of 10 km from the seismic vessel (estimated received level 143 dB re 1 µPa peak-to-peak).

Castellote et al. (2012a) found that vocalizing fin whales in the Mediterranean left the area where a seismic survey was being conducted and that their displacement persisted beyond the completion of the survey. These studies demonstrate that even low levels of noise received far from the noise source can induce behavioral responses.

6.2.10.1.2 Odontocetes

Madsen et al. (2006) and Miller et al. (2009) tagged and monitored eight sperm whales in the Gulf of Mexico exposed to seismic airgun surveys. Sound sources were approximately 2 to 7 nm away from the whales and, based on multipath propagation received levels, were as high as 162 dB SPL re 1 µPa with energy content greatest between 0.3 kHz to 3.0 kHz (Madsen et al. 2006). The whales showed no horizontal avoidance, although the whale that was approached most closely had an extended resting period and did not resume foraging until the airguns had ceased firing (Miller et al. 2009). The remaining whales continued to execute foraging dives throughout exposure, however swimming movements during foraging dives were 6 percent lower during exposure than control periods, suggesting subtle effects of noise on foraging behavior (Miller et al. 2009). Captive bottlenose dolphins sometimes vocalized after an exposure to impulsive sound from a seismic watergun (Finneran and Schlundt 2010; Thompson et al. 2013).

6.2.10.2 *Behavioral Reactions of Marine Mammals to Non-Impulsive Sources*

The following sections describe the behavioral reactions of marine mammals to non-impulsive sound sources such as sonar.

6.2.10.2.1 Mysticetes

Specific to U.S. Navy systems using low frequency sound, studies were undertaken pursuant to the Navy's Low Frequency Sound Scientific Research Program. These studies found only short-term responses to low frequency sound by mysticetes (fin, blue, and humpback whales) including changes in vocal activity and avoidance of the source vessel (Clark and Fristrup 2001; Croll et al. 2001b; Fristrup et al. 2003; Miller et al. 2000; Nowacek et al. 2007). Work by (Risch et al. 2012) found that humpback whale vocalizations were reduced concurrently with pulses from the low frequency Ocean Acoustic Waveguide Remote Sensing (OAWRS) source located approximately 200 km away. However, (Gong et al. 2014), disputes these findings, suggesting that (Risch et al. 2012) mistakes natural variations in humpback whale song occurrence for changes caused by OAWRS activity approximately 200 km away. (Risch et al. 2014) responded to (Gong et al. 2014) and highlighted the context-dependent nature of behavioral responses to acoustic stressors.

Baleen whales exposed to moderate low-frequency signals demonstrated no variation in foraging activity (Croll et al. 2001b). However, five out of six North Atlantic right whales exposed to an acoustic alarm interrupted their foraging dives, although the alarm signal was long in duration, lasting several minutes, and purposely designed to elicit a reaction from the animals as a prospective means to protect them from ship strikes (Nowacek et al. 2004). Although the animal's received sound pressure level was similar in the latter two studies (133 to 150 dB re 1 µPa), the frequency, duration, and temporal pattern of signal presentation were different. Additionally, the right whales did not respond to playbacks of either right whale social sounds or vessel noise, highlighting the importance of the sound characteristics, species differences, and individual sensitivity in producing a behavioral reaction.

Low-frequency signals of the Acoustic Thermometry of Ocean Climate sound source were not found to affect dive times of humpback whales in Hawaiian waters (Frankel and Clark 2000) or to overtly affect elephant seal dives off California (Costa et al. 2003). However, they did produce subtle effects that varied in direction and degree among the individual seals, again illustrating the uncertain nature of behavioral effects and consequent difficulty in defining and predicting them.

Despite previous assumptions based on vocalizations and anatomy that blue whales predominantly hear low-frequency sounds below 400 Hz (Croll et al. 2001b; Oleson et al. 2007b; Stafford and Moore 2005a), preliminary results from the 2010 and 2011 field seasons of an ongoing behavioral response study in Southern California waters indicated that in some cases and at low received levels, tagged blue whales responded to mid-frequency sonar. However, those responses were mild and there was a quick return to their baseline activity (Southall et al. 2011a). Blue whales appeared to ignore sonar transmissions at received levels lower than approximately 150 dB and generally ignored received levels greater than these when they were engaged in feeding behavior (Southall et al. 2011a).

Goldbogen et al. (2013) used DTAGs to test the response of blue whales in the Southern California Bight to playbacks of simulated MFA sonar. Source levels of simulated sonar and control sounds (pseudo-random noise or PRN) in the 3.5 to 4.0 kHz range were ramped up in 3 dB increments from 160 to 210 dB re 1 µPa. Responses varied depending on the whales' prior behavioral state: surface feeding whales showed no response, while deep feeding whales and whales that were not feeding were affected. Responses among affected animals ranged from termination of deep foraging dives to prolonged mid-water dives. The reactions were context dependent, leading the authors to conclude a combination of received sound level and the behavioral state of the animal are likely to influence behavioral response. The authors note that whales responded even at low SPLs, suggesting that received level alone may not be a reliable predictor of behavior. Goldbogen et al. (2013) noted that behavioral responses observed were temporary and whales typically resumed normal behavior quickly after the cessation of sound exposure. Perhaps the most significant reponse documented in the study resulted from an experiment involving PRN rather than simulated sonar, which corresponded with a blue whale terminating a foraging bout. The more significant reaction to PRN may be indicative of habituation to mid-frequency sonar signals; the authors noted that the responses they documented were in a geographical region with a high level of naval activity and where mid-frequency sonar use is common.

Melcon et al. (2012) tested whether MFA sonar and other anthropogenic noises in the mid-frequency band affected the "D-calls" produced by blue whales in the Southern California Bight. The authors used passive acoustic monitoring data recorded with stationary High-frequency Acoustic Recording Packages in the Southern California Bight. The likelihood of an animal calling decreased with the increased received level of mid-frequency sonar, beginning at a sound pressure level of approximately 110 to 120 dB re 1 µPa. Observations indicated that after sonar cessation, blue whales start producing D calls again. The authors concluded that blue whales heard and devoted attention to the sonar, despite its high frequency (relative to their putative hearing sensitivity) and its low received level. However, the authors noted that while D calls are typically associated with blue whale foraging behavior, they were unable to determine if

suppression of D calls reflected a change in their feeding performance or abandonment of foraging behavior.

Martin et al. (2015) used bottom mounted hydrophone arrays to estimate minke whale densities in the Pacific Missile Range Facility (PMRF) located off Kauai, Hawaii before, during, and after Navy training events involving active sonar. The study indicated minke whales decreased calling during the transmission of MFA sonar, but could not determine whether or not the whales left the area. The authors also suggested the presence of Naval surface ships during MFA transmission should be considered as a factor in the cessation of calling, rather than assuming the MFA sonar itself is the sole cause for the cessation of calling.

6.2.10.2.2 Odontocetes

From 2007 to present, behavioral response studies have been conducted through the collaboration of various research organizations in the Bahamas, Southern California, Mediterranean, Cape Hatteras, and Norwegian waters. These studies attempted to define and measure responses of beaked whales and other cetaceans to controlled exposures of sonar and other sounds to better understand their potential impacts. Results from the 2007 to 2008 study conducted near the Bahamas showed a change in diving behavior of an adult Blainville's beaked whale to playback of mid-frequency source and predator sounds (Boyd et al. 2008; Southall et al. 2009; Tyack et al. 2011c). Reaction to mid-frequency sounds included premature cessation of clicking, termination of a foraging dive, and a slower ascent rate to the surface. Preliminary results have been presented for the behavioral response study in Southern California waters (e.g., (Boyd et al. 2008; Southall et al. 2013; Southall et al. 2012; Southall et al. 2011a).

For example, Stimpert et al. (2014) tagged a Baird’s beaked whale and exposed it to simulated mid-frequency sonar. Some changes in the animal’s dive behavior and locomotion were observed when received level reached 127 dB re 1µPa. Deruiter et al. (2013b) presented results from two Cuvier’s beaked whales that were tagged and exposed to simulated MFA sonar during the 2010 and 2011 field seasons of the southern California behavioral response study. The 2011 whale was also incidentally exposed to MFA sonar from a distant naval exercise. Received levels from the MFA sonar signals from the controlled and incidental exposures were calculated as 84 to 144 and 78 to 106 dB re 1 µPa root mean square, respectively. Both whales showed responses to the controlled exposures, ranging from initial orientation changes to avoidance responses characterized by energetic fluking and swimming away from the source. However, the authors did not detect similar responses to incidental exposure to distant naval sonar exercises at comparable received levels, indicating that context of the exposures (e.g., source proximity, controlled source ramp-up) may have been a significant factor. Cuvier's beaked whale responses suggested particular sensitivity to sound exposure as consistent with results for Blainville’s beaked whale. Similarly, beaked whales exposed to sonar during British training exercises stopped foraging (DSTL 2007).

Miller et al. (2011) reported on behavioral responses of pilot whales, killer whales, and sperm whales off Norway to Norwegian Navy mid-frequency sonar sources (a 3-year effort called the 3S experiments) (see also (Antunes et al. 2014); (Kuningas et al. 2013); (Kvadsheim et al. 2011); (Miller et al. 2012); (Miller et al. 2014); (Sivle et al. 2012). Reactions at different distances and received levels were variable, and types of responses observed included cessation of feeding,

avoidance, changes in vocalizations, and changes in dive behavior. Some exposures elicited no observable reactions, and others resulted in brief or minor reactions, such as minor changes in vocalizations or locomotion. The experimental exposures occurred across different behavioral and environmental contexts, which may have played a role in the type of response observed, at least for killer whales (Miller et al. 2014). Some aspects of the experiment differ from typical Navy actions and may have exacerbated observed reactions; for example, animals were directly approached by the source vessel, researchers conducted multiple approaches toward the same animal groups over the course of each session, some exposures were conducted in bathymetrically restricted areas, and, in some cases, researchers "leapfrogged" the boat to repeatedly move ahead of the animals in order to repeatedly approach animals on their travel path. For example, separation of a killer whale calf from its mother occurred during the fifth vessel approach towards a killer whale group in a fjord. In contrast, U.S. Navy vessels avoid approaching marine mammals head-on, and vessels will maneuver to maintain a distance of at least 500 yd. (457 m) from observed animals. Furthermore, Navy mitigation measures would dictate powerdown of hull-mounted ASW sonars within 1,000 yd. (914m) of marine mammals and ultimately shutdown if an animal is within 200 yd. (183 m).

In the 2007 to 2008 Bahamas study, playback sounds of a potential predator— a killer whale— resulted in a similar but more pronounced reaction, which included longer inter-dive intervals and a sustained straight-line departure of more than 20 km from the area. The authors noted, however, that the magnified reaction to the predator sounds could represent a cumulative effect of exposure to the two sound types since killer whale playback began approximately 2 hours after mid-frequency source playback (Boyd et al. 2008; Tyack et al. 2011c). In contrast, preliminary analyses suggest that none of the pilot whales or false killer whales in the Bahamas showed an avoidance response to controlled exposure playbacks (Southall et al. 2009).

Through analysis of the behavioral response studies, a preliminary overarching effect of greater sensitivity to all anthropogenic exposures was seen in beaked whales compared to the other odontocetes studied (Southall et al. 2009). Therefore, recent studies have focused specifically on beaked whale responses to MFA sonar transmissions or controlled exposure playback of simulated sonar on various military ranges (Claridge and Durban 2009; DSTL 2007; McCarthy et al. 2011; Moretti 2009; Tyack et al. 2011c). In the Bahamas, Blainville's beaked whales located on the range will move off-range during MFA sonar use and return only after the sonar transmissions have stopped, sometimes taking several days to do so (Claridge and Durban 2009; McCarthy et al. 2011; Moretti 2009; Tyack et al. 2011c). Moretti et al. (2014) used recordings from seafloor mounted hydrophones at the Atlantic Undersea Test and Evaluation Center (AUTEC) to analyze the probability of Blainsville's beaked whale dives before, during, and after Navy sonar exercises. They developed an empirical risk function and predicted a 0.5 probability of disturbance at received levels of 150 dB.

Claridge (2013) used photo-recapture methods to estimate population abundance and demographics of Blainville's beaked whale (Mesoplodon densirostris) in the Bahamas at two sample locations; one within the bounds of the AUTEC where sonar training occurs and the second along the edge of Abaco Island approximately 170 km to the north. To investigate the potential effect of beaked whale exposure to MFA sonar, Claridge assumed that the two sample sites should have equal potential abundances and hypothesized that a lower abundance found at

the AUTEC was due to either reduced prey availability at AUTEC or due to population level effects from the exposure to MFA sonar at AUTEC.

There are two major issues with this study. First, all of the re-sighted whales during the 5-year study at both sites were female. Claridge acknowledges that this can lead to a negative bias in the estimation of abundances. It has been shown in other cetacean species that females with calves may prefer "nursery" habitats or form nursery groups with other mother-calf pairs (e.g., (Claridge 2006; Scott et al. 1990; Weir et al. 2008)). It may be that the site at Abaco is a preferred site for females with calves, while the site at AUTEC is not, and therefore over the 5-year study period fewer females with calves were observed at AUTEC as these females went elsewhere in the area during the 3-year weaning period. In addition, Marques et al. (2009) estimated the Blainville's beaked whale population at AUTEC to be between 22.5 and 25.3 animals per 1,000 km^2 . This density was estimated over 6 days using passive acoustic methods, which is a method Claridge identified as one that may be better for estimating beaked whale densities than visual methods. The results at AUTEC are also biased by reduced effort and a shorter overall study period that did not capture some of the emigration/immigration trends Claridge identified at Abaco. For these reasons among others, it is unclear whether there are significant differences in the abundances between the two sites.

Second, Claridge assumed that the two sites are identical and therefore should have equal potential abundances; Abaco is a "control" site with the difference being the use of sonar at AUTEC. Although the sample boundaries at each location were drawn to create samples "of comparable size," there are differences between the two sample area locations as follows: the Abaco site is along a leeward shore, AUTEC is windward; the Abaco sample area is a long narrow margin along a canyon wall, the rectangular AUTEC sample site is a portion of a deep and landlocked U-shaped trough. In addition to the physical differences, Claridge notes that it remains unclear whether or not variation in productivity between sites influenced what she refers to as the substantial differences in abundance. Claridge reports that a study investigating prey distributions at her sample locations was unable to sample prey at the beaked whale foraging depth. Claridge dismisses the possibility of differences in prey availability between the sites noting that there is no supporting evidence that prey availability differs between the two sites. As this study illustrates, the multiple and complex factors required by investigations of potential long-term cause and effect from actions at sea require a comprehensive assessment of all factors influencing potential trends in species abundances that are not likely attributable to a single cause and effect.

In the Caribbean, research on sperm whales in 1983 coincided with the U.S. intervention in Grenada. Sperm whales interrupted their activities by stopping echolocation and leaving the area. This response was assumed to be the result of underwater sounds originating from submarine mid to high-frequency sonar signals (Watkins et al. 1985b; Watkins and Schevill 1975a). The authors did not provide any sound levels associated with these observations, although they did note getting a similar reaction from banging on their boat hull. It was unclear if the sperm whales were reacting to the sonar signal itself or to a potentially new unknown sound as had been demonstrated on another occasion during which sperm whales in the Caribbean stopped vocalizing when presented with sounds from nearby acoustic pingers (Watkins and Schevill 1975a).

Researchers at the Navy's Marine Mammal Program facility in San Diego, California have conducted a series of controlled experiments on bottlenose dolphins and beluga whales to study TTS (Finneran 2010; Finneran 2011; Finneran et al. 2001; Finneran et al. 2003; Finneran et al. 2010; Finneran and Schlundt 2004; Schlundt et al. 2000). Ancillary to the TTS studies, scientists evaluated whether the marine mammals performed their trained tasks when prompted, during and after exposure to mid-frequency tones. Altered behavior during experimental trials usually involved refusal of animals to return to the site of the sound stimulus. This refusal included what appeared to be deliberate attempts to avoid a sound exposure or to avoid the location of the exposure site during subsequent tests (Finneran et al. 2002; Schlundt et al. 2000). Bottlenose dolphins exposed to 1-second tones exhibited short-term changes in behavior above received sound levels of 178 to 193 dB re 1 µPa root mean square, and beluga whales did so at received levels of 180 to 196 dB re 1 µPa and above. In some instances, animals exhibited aggressive behavior toward the test apparatus (Ridgway et al. 1997; Schlundt et al. 2000). While these studies were not designed to test avoidance behavior and animals were commonly reinforced with food, the controlled environment and ability to measure received levels provide insight on received levels at which animals will behaviorally responds to noise sources. More recently, a controlled-exposure study was conducted with U.S. Navy bottlenose dolphins at the Navy Marine Mammal Program facility specifically to study behavioral reactions to simulated mid-frequency sonar (Houser et al. 2013). Animals were trained to swim across a pen, touch a panel, and return to the starting location. During transit, a simulated mid-frequency sonar signal was played. Behavioral reactions were more likely with increasing received level and included increased respiration rates, fluke or pectoral fin slapping, and refusal to participate, among others. From these data, it was determined that bottlenose dolphins were more likely to respond to the initial trials, but habituated to the sound over the course of 10 trials except at the highest received levels. All dolphins responded at the highest received level (185 dB re 1 µPa).

Studies with captive harbor porpoises showed increased respiration rates upon introduction of acoustic alarms, such as those used on fishing nets to help deter marine mammals from becoming caught or entangled (Kastelein et al. 2001; Kastelein et al. 2006a) and emissions for underwater data transmission (Kastelein et al. 2005). However, exposure of the same acoustic alarm to a striped dolphin under the same conditions did not elicit a response (Kastelein et al. 2006b), again highlighting the importance in understanding species differences in the tolerance of underwater noise (Southall et al. 2007b). Henderson et al. (2014) observed behavioral responses of delphinids to MFA sonar in the Southern California Bight from 2004 to 2008. The authors observed responses ranging from changes in behavioral state or direction of travel, to changes in vocalization activity. Behavioral responses were generally observed at received sound pressure levels ranging from 107 to 117 dB_{rms} re: 1 µPa. We are not reasonably certain that exposure to such sound pressure levels will elicit a substantive behavioral reaction and rise to the level of take per the ESA.

6.2.10.3 *Behavioral Reactions of Marine Mammals to Vessels*

Sound emitted from large vessels, such as shipping and cruise ships, is the principal source of low-frequency noise in the ocean today, and marine mammals are known to react to or be affected by that noise (Foote et al. 2004; Hatch and Wright 2007; Hildebrand 2005; Holt et al. 2008b; Kerosky et al. 2013; Melcon et al. 2012; Richardson et al. 1995c). As noted previously, in

the Inland Waters of Puget Sound, Erbe et al. (2012) estimated the maximum annual underwater sound exposure level from vessel traffic near Seattle was 215 dB re 1 µPa^2-s. Bassett et al. (2010) measured mean sound pressure levels at Admiralty Inlet from commercial shipping at 117 dB re 1 µPa with a maximum exceeding 135 dB re 1 µPa on some occasions.

In short-term studies, researchers have noted changes in resting and surface behavior states of cetaceans to whale watching vessels (Acevedo 1991b; Aguilar Soto et al. 2006; Arcangeli and Crosti 2009; Au and Green 2000; Christiansen et al. 2010; Erbe 2002b; Noren et al. 2009; Stensland and Berggren 2007; Stockin et al. 2008; Williams and Noren 2009). Noren et al. (2009) conducted research in the San Juan Islands in 2005 and 2006 and their findings suggested that close approaches by vessels impacted the whales' behavior and that the whale-watching guideline minimum approach distance of 100 m may be insufficient in preventing behavioral responses. Most studies of this type are opportunistic and have only examined the short-term response to vessel sound and vessel traffic (Magalhaes et al. 2002; Noren et al. 2009; Richardson and Wursig 1995; Watkins 1981d).

Long-term and cumulative implications of vessel sound on marine mammals remains largely unknown. Clark et al. (2009) provided a discussion on calculating the cumulative impacts of anthropogenic noise on baleen whales and estimated the noise from the passage of two vessels could reduce the optimal communication space for North Atlantic right whales by 84 percent (see also (Hatch et al. 2012)).

Bassett et al. (2012) recorded vessel traffic over a period of just under a year as large vessels passed within 20 km of a hydrophone site located at Admiralty Inlet in Puget Sound. During this period there were 1,363 unique Automatic Identification System transmitting vessels recorded. Navy vessels, given they are much fewer in number, are a small component of overall vessel traffic and vessel noise in most areas where they operate and this is especially the case in the Action Area (see Mintz and Filadelfo (2011) concerning a general summary for the U.S. Exclusive Economic Zone). In addition, Navy combatant vessels have been designed to generate minimal noise and use ship quieting technology to elude detection by enemy passive acoustic devices (Mintz and Filadelfo 2011; Southall et al. 2005).

6.2.10.3.1 Mysticetes

Fin whales may alter their swimming patterns by increasing speed and heading away from a vessel, as well as changing their breathing patterns in response to a vessel approach (Jahoda et al. 2003). Vessels that remain 328 ft. (100 m) or farther from fin and humpback whales were largely ignored in one study where whale watching activities are common (Watkins 1981b). Only when vessels approached more closely did the fin whales in this study alter their behavior by increasing time at the surface and exhibiting avoidance behaviors. Other studies have shown when vessels are near, some but not all fin whales change their vocalizations, surface time, swimming speed, swimming angle or direction, respiration rates, dive times, feeding behavior, and social interactions (Au and Green 2000; Castellote et al. 2012c; Richter et al. 2003; Williams et al. 2002b).

Based on passive acoustic recordings and in the presence of sounds from passing vessels, Melcon et al. (2012) reported that blue whales had an increased likelihood of producing certain types of calls. Castellote et al. (2012c) demonstrated that fin whales' songs had shortened duration and decreased bandwidth, center frequency, and peak frequency in the presence of high shipping noise levels. It is not known if these changes in vocal behavior corresponded to other behaviors.

In the Watkins (1981b) study, humpback whales did not exhibit any avoidance behavior but did react to vessel presence. In a study of regional vessel traffic, Baker et al. (1983) found that when vessels were in the area, the respiration patterns of the humpback whales changed. The whales also exhibited two forms of behavioral avoidance: horizontal avoidance (changing direction or speed) when vessels were between 1.24 and 2.48 mi. (2,000 and 4,000 m) away, and vertical avoidance (increased dive times and change in diving pattern) when vessels were within approximately 1.2 mi. (2,000 m; (Baker and Herman 1983)). Similar findings were documented for humpback whales when approached by whale watch vessels in Hawaii (Au and Green 2000).

Gende et al. (2011) reported on observations of humpback whales in inland waters of Southeast Alaska subjected to frequent cruise ship transits (i.e., in excess of 400 transits in a 4-month season in 2009). The study was focused on determining if close encounter distance was a function of vessel speed. The reported observations, however, seem in conflict with other reports of avoidance at much greater distance so it may be that humpback whales in those waters are more tolerant of vessels (given their frequency) or are engaged in behaviors, such as feeding, that they are less willing to abandon. This example again highlights that context is critical for predicting and understanding behavioral reactions as concluded by Southall et al. (2007b) and Ellison et al. (2012).

Sei whales have been observed ignoring the presence of vessels and passing close to them (National Marine Fisheries Service 1993). In the presence of approaching vessels, blue whales perform shallower dives accompanied by more frequent surfacing, but otherwise do not exhibit strong reactions (Calambokidis et al. 2009). Minke whales in the Antarctic did not show any apparent response to a survey vessel moving at normal cruising speeds (about 12 knots) at a distance of 5.5 nm; however, when the vessel drifted or moved at very slow speeds (about 1 knot), many whales approached it (Leatherwood et al. 1982a).

Although not expected to be in the MITT Action Area, North Atlantic right whales tend not to respond to the sounds of oncoming vessels (Nowacek et al. 2004) and therefore might provide insight to behavioral responses of other baleen whales. North Atlantic right whales continue to use habitats in high vessel traffic areas (Nowacek et al. 2004). Studies show that North Atlantic right whales demonstrate little if any reaction to sounds of vessels approaching or the presence of the vessels themselves (Nowacek et al. 2004; Terhune and Verboom 1999). Although this may minimize potential disturbance from passing ships, it does increase the whales' vulnerability to potential ship strike. The regulated approach distance for North Atlantic right whales is 500 yards (yd.) (457 m) (NMFS 1997).

Using historical records, Watkins (1986) showed that the reactions of four species of mysticetes to vessel traffic and whale watching activities in Cape Cod had changed over the 25-year period examined (1957 through 1982). Reactions of minke whales changed from initially more positive

reactions, such as coming towards the boat or research equipment to investigate, to more 'uninterested' reactions towards the end of the study. Finback [fin] whales, the most numerous species in the area, showed a trend from initially more negative reactions, such as swimming away from the boat with limited surfacing, to more uninterested (ignoring) reactions allowing boats to approach within 98.4 ft. (30 m). Right whales showed little change over the study period, with a roughly equal number of reactions judged to be negative and uninterested; no right whales were noted as having positive reactions to vessels. Humpback whales showed a trend from negative to positive reactions with vessels during the study period. The author concluded that the whales had habituated to the human activities over (Watkins 1986).

Mysticetes have been shown to both increase and decrease calling behavior in the presence of vessel noise. An increase in feeding call rates and repetition by humpback whales in Alaskan waters was associated with vessel noise (Doyle et al. 2008). Melcon et al. (2012) also recently documented that blue whales increased the proportion of time spent producing certain types of calls when vessels were present. Conversely, decreases in singing activity by humpback whales have been noted near Brazil due to boat traffic (Sousa-Lima and Clark 2008). The Central North Pacific stock of humpback whales is the focus of whale-watching activities in both its feeding grounds (Alaska) and breeding grounds (Hawaii). Regulations addressing minimum approach distances and vessel operating procedures are in place in Hawaii, however, there is still concern that whales may abandon preferred habitats if the disturbance is too high (Allen and Angliss 2010b).

6.2.10.3.2 Odontocetes

Sperm whales generally react only to vessels approaching within several hundred meters; however, some individuals may display avoidance behavior, such as quick diving (Magalhaes et al. 2002; Wursig et al. 1998). One study showed that after diving, sperm whales showed a reduced timeframe from when they emitted the first click than before vessel interaction (Richter et al. 2006). Small whale-watching and research vessels generate more noise in higher frequency bands and are more likely to approach odontocetes directly, and to spend more time near the individual whale. Reactions to Navy vessels are not well documented, but smaller whale-watching and research boats have been shown to cause these species to alter their breathing intervals and echolocation patterns.

Wursig et al. (1998) reported most *Kogia* species and beaked whales react negatively to vessels by quick diving and other avoidance maneuvers. Cox et al. (2006) noted very little information is available on the behavioral impacts of vessels or vessel noise on beaked whales. A single observation of vocal disruption of a foraging dive by a tagged Cuvier's beaked whale documented when a large noisy vessel was opportunistically present, suggests that vessel noise may disturb foraging beaked whales (Aguilar Soto et al. 2006). Tyack et al. (2011b) noted the result of a controlled exposure to pseudorandom noise suggests beaked whales would respond to vessel noise at similar received levels to those noted previously for mid-frequency sonar.

Most delphinids react neutrally to vessels, although both avoidance and attraction behavior is known (Hewitt 1985a; Wursig et al. 1998). Avoidance reactions include a decrease in resting behavior or change in travel direction (Bejder et al. 2006a). Incidence of attraction includes harbor porpoises approaching a vessel and common, rough-toothed, and bottlenose dolphins bow

riding and jumping in the wake of a vessel (Norris and Prescott 1961; Shane et al. 1986) (Ritter 2002; Wursig et al. 1998). A study of vessel reactions by dolphin communities in the eastern tropical Pacific found that populations that were often the target of tuna purse-seine fisheries (spotted, spinner and common dolphins) show evasive behavior when approached; however populations that live closer to shore (within 100 nm; coastal spotted and bottlenose dolphins) that are not set on by purse-seine fisheries tend to be attracted to vessels (Archer et al. 2010a; Archer et al. 2010b). Pirotta et al. (2015) quantified the effect of boat disturbance on bottlenose dolphin foraging and determined that foraging activity was more affected by boat presence than noise level.

Killer whales, the largest of the delphinids, are targeted by numerous small whale-watching vessels in the Pacific Northwest. For the 2012 season, it was reported that 1,590 vessel incidents were possible violations of the federal vessel approach regulations or MMPA and ESA laws as well (Eisenhardt 2013). Research suggests that whale-watching distances may be insufficient to prevent behavioral disturbances due to vessel noise (Noren et al. 2009). In 2012, there were 79 U.S. and Canadian commercial whale watch vessels in the Haro Strait region (Eisenhardt 2013). These vessels have measured source levels that ranged from 145 to 169 dB re 1 µPa at 1 m. The sound they produce underwater has the potential to result in behavioral disturbance, interfere with communication, and affect the killer whales' hearing (Erbe 2002b). Killer whales foraged significantly less and traveled significantly more when boats were within 328 ft. (100 m) (Kruse 1991b; Lusseau et al. 2009; Trites and Bain 2000; Williams and Noren 2009; Williams et al. 2002b). These short-term feeding activity disruptions may have important long-term population-level effects (Lusseau et al. 2009; Noren et al. 2009). The reaction of the killer whales to whale-watching vessels may be in response to the vessel pursuing them, rather than to the noise of the vessel itself, or to the number of vessels in their proximity.

Odontocetes have been shown to make short-term changes to vocal parameters such as intensity (Holt et al. 2008a) as an immediate response to vessel noise, as well as increase the pitch, frequency modulation, and length of whistling (May-Collado and Wartzok 2008). Likewise, modification of multiple vocalization parameters has been shown in belugas residing in an area known for high levels of commercial traffic. These animals decreased their call rate, increased certain types of calls, and shifted upward in frequency content in the presence of small vessel noise (Lesage et al. 1999). Another study detected a measurable increase in the amplitude of their vocalizations when ships were present (Scheifele et al. 2005). Killer whales off the northwestern coast of the United States have been observed to increase the duration of primary calls once a threshold in observed vessel density (e.g., whale watching) was reached, which has been suggested as a response to increased masking noise produced by the vessels (Foote et al. 2004). On the other hand, long-term modifications to vocalizations may be indicative of a learned response to chronic noise, or of a genetic or physiological shift in the populations. For example, the source level of killer whale vocalizations has been shown to increase with higher background noise levels associated with vessel traffic (Hotchkin and Parks 2013). In addition, calls with a high-frequency component have higher source levels than other calls, which may be related to behavioral state, or may reflect a sustained increase in background noise levels (Holt et al. 2008a).

6.2.10.4 *Behavioral Reactions of Marine Mammals to Aircraft and Missile Overflight*

Thorough reviews on the behavioral reactions of marine mammals to aircraft and missile overflight are presented in Richardson et al. (1995c), Efroymson et al. (2000), Luksenburg and Parsons (2009), and Holst et al. (2011). The most common responses of cetaceans to aircraft overflights were short surfacing durations, abrupt dives, and percussive behavior (breaching and tail slapping) (Nowacek et al. 2007). Other behavioral responses such as flushing and fleeing the area of the source of the noise have also been observed (Holst et al. 2011; Manci et al. 1988). Richardson et al. (1995c) noted that marine mammal reactions to aircraft overflight largely consisted of opportunistic and anecdotal observations. These observations lack a clear distinction between reactions potentially caused by the noise of the aircraft and the visual cue an aircraft presents. In addition, it was suggested that variations in the responses noted were due to other undocumented factors associated with overflight (Richardson et al. 1995c). These factors could include aircraft type (single engine, multi-engine, jet turbine), flight path (centered on the animal, off to one side, circling, level and slow), environmental factors such as wind speed, sea state, cloud cover, and locations where native subsistence hunting continues.

6.2.10.4.1 Mysticetes

Mysticetes either ignore or occasionally dive in response to aircraft overflights (Efroymson et al. 2000; Koski et al. 1998). Richardson et al. (1995c) reported that while data on the reactions of mysticetes is meager and largely anecdotal, there is no evidence that single or occasional aircraft flying above mysticetes causes long-term displacement of these mammals. In general, overflights above 1,000 ft. (305 m) do not cause a reaction.

Bowhead whales in the Beaufort Sea exhibited a transient behavioral response to fixed-wing aircraft and vessels. Reactions were frequently observed at less than 1,000 ft. (305 m) above sea level, infrequently observed at 1,500 ft. (457 m), and not observed at 2,000 ft. (610 m) above sea level (Richardson et al. 1995c). Bowhead whales reacted to helicopter overflights by diving, breaching, changing direction or behavior, and altering breathing patterns. Behavioral reactions decreased in frequency as the altitude of the helicopter increased to 492 ft. (150 m) or higher. It should be noted that bowhead whales may have more acute responses to anthropogenic activity than many other marine mammals since these animals are often presented with limited egress due to limited open water between ice floes. Additionally, many of these animals may be hunted by Alaska Natives, which could lead to animals developing additional sensitivity to human noise and presence.

6.2.10.4.2 Odontocetes

Variable responses to aircraft have been observed in toothed whales, though overall little change in behavior has been observed during flyovers. Toothed whale responses to aircrafts include diving, slapping the water with their flukes or flippers, swimming away from the direction of the aircraft, or not visibly reacting (Richardson et al. 1995c).

During standard marine mammal surveys at an altitude of 750 ft. (229 m), some sperm whales remained on or near the surface the entire time the aircraft was in the vicinity, while others dove immediately or a few minutes after being sighted. Other authors have corroborated the variability in sperm whales' reactions to fixed-wing aircraft or helicopters (Green et al. 1992; Richter et al. 2006; Richter et al. 2003; Smultea et al. 2008; Wursig et al. 1998). In one study, sperm whales

showed no reaction to a helicopter until they encountered the downdrafts from the rotors (Richardson et al. 1995c). A group of sperm whales responded to a circling aircraft (altitude of 800 to 1,100 ft. [244 to 335 m]) by moving closer together and forming a defensive fan-shaped semicircle, with their heads facing outward. Several individuals in the group turned on their sides, apparently to look up toward the aircraft (Smultea et al. 2008). Whale-watching aircraft apparently caused sperm whales to turn more sharply but did not affect blow interval, surface time, time to first click, or the frequency of aerial behavior (Richter et al. 2003). Navy aircraft do not fly at low altitude, hover over, or follow whales and so are not expected to evoke this type of response.

Smaller delphinids generally react to overflights either neutrally or with a startle response (Wursig et al. 1998). The same species that show strong avoidance behavior to vessel traffic (*Kogia* species and beaked whales) also react to aircraft (Wursig et al. 1998). Beluga whales reacted to helicopter overflights by diving, breaching, changing direction or behavior, and altering breathing patterns to a greater extent than mysticetes in the same area (Patenaude et al. 2002). These reactions increased in frequency as the altitude of the helicopter dropped below 492 ft. (150 m).

6.2.11 Repeated Exposures of Marine Mammals

Navy sonar systems are generally deployed from highly mobile vessels or in-water devices which do not directly target marine mammals. Further, the typical duty cycle with most tactical anit-submarine warefare is lower than used in the controlled exposure experiments described above, transmitting about once per minute (Navy 2013). For example, a typical Navy vessel with hull mounted MFA sonar would travel over 0.3 kilometers between pings (based on a speed of 10 knots/hr and transmission rate of 1 ping/min). Based on this distance traveled and potential avoidance behavior of acoustically exposed animals, we expect repeat acoustic exposures capable of eliciting a behavioral response to an individual over a brief period of time to be rare. For sonar devices that are stationary (e.g. dipped sonar), due to the duty cycle, duration of active transmission in a specific location, and mitigation measures (e.g. avoidance of visible marine mammals), we would not expect repeated exposures.

Some individuals may be exposed to multiple sound-producing activities over a season, year, or life stage. Repeated exposure to acoustic and other anthropogenic stimuli has been studied in several cases, especially as related to vessel traffic and whale watching. Common dolphins in New Zealand responded to dolphin-watching vessels by interrupting foraging and resting bouts, and took longer to resume behaviors in the presence of the vessel (Stockin 2008). Bejder et al. (2006a) studied responses of bottlenose dolphins to vessel approaches and found shorter lasting reactions in populations exposed to higher levels of vessel traffic. The authors indicated that lesser reactions in populations of dolphins regularly subjected to high levels of vessel traffic could be a sign of habituation, or it could be that the more sensitive animals in this population previously abandoned the area of higher human activity.

Marine mammals exposed to high levels of human activities may leave the area, habituate to the activity, or tolerate the disturbance and remain in the area. Individual marine mammals that are more tolerant may stay in a disturbed area, whereas individuals that are more sensitive may leave for areas with less human disturbance. Animals that remain throughout the disturbance may be

unable to leave the area for a variety of physiological or environmental reasons. However, given the highly migratory, wide ranging life histories, and open ocean environments of the species considered in this Opinion, we do not believe this will result from Navy training and testing activities in the MITT Action Area. Longer-term displacement can lead to changes in abundance or distribution patterns of the species in the affected region if they do not become acclimated to the presence of the sound (Bejder et al. 2006b; Blackwell et al. 2004; Teilmann et al. 2006). Gray whales in Baja California abandoned a historical breeding lagoon in the mid-1960s due to an increase in dredging and commercial shipping operations. Whales did repopulate the lagoon after shipping activities had ceased for several years (Bryant et al. 1984). Over a shorter time scale, studies on the Atlantic Undersea Test and Evaluation Center instrumented range in the Bahamas have shown that some Blaineville's beaked whales may be resident during all or part of the year in the area, and that individuals may move off of the range for several days during and following a sonar event. However animals are thought to continue feeding at short distances (a few kilometers) from the range out of the louder sound fields (less than 157 dB re 1 µPa) (McCarthy et al. 2011; Tyack et al. 2011c). Mysticetes in the northeast tended to adjust to vessel traffic over a number of years, trending towards more neutral responses to passing vessels (Watkins 1986) indicating that some animals may habituate or otherwise learn to cope with high levels of human activity. Nevertheless, the long-term consequences of these habitat utilization changes are unknown, and likely vary depending on the species, geographic areas, and the degree of acoustic or other human disturbance.

Moore and Barlow (2013) have noted a decline in beaked whales in a broad area of the Pacific Ocean area out to 300 nm from the coast and extending from the Canadian-U.S. border to the tip of Baja Mexico. There are scientific caveats and limitations to the data used for that analysis, as well as oceanographic and species assemblage changes not thoroughly addressed in Moore and Barlow (2013), although the authors suggest Navy sonar as one possible explanation for the apparent decline in beaked whale numbers over that broad area. In the small portion of the Pacific coast overlapping the Navy's SOCAL Range Complex, long-term residency by individual Cuvier's beaked whales and documented higher densities of beaked whales provide indications that the proposed decline in numbers elsewhere along the Pacific coast is not apparent where the Navy has been intensively training with sonar and other systems for decades. While it is possible that a downward trend in beaked whales may have gone unnoticed at the range complex (due to a lack of survey precision) or that beaked whale densities may have been higher before the Navy began using sonar more than 60 years ago, there is no data available to suggest that beaked whale numbers have declined on the range where Navy sonar use has routinely occurred. As Moore and Barlow (2013) point out, it remains clear that the Navy range in SOCAL continues to support high densities of beaked whales. Furthermore, a large part of the U.S. West Coast Action Area used by Moore and Barlow (2013) in their assessment of possible reasons for the decline include vast areas where the Navy does not conduct in-water training with sonar or explosives.

Establishing a causal link between anthropogenic noise, animal communication, and individual impacts as well as population viability is difficult to quantify and assess (McGregor 2013) (Read et al. 2014). Assessing the effects of sounds, both individually and cumulatively, on marine species is difficult because responses depend on a variety of factors incuding age class, prior experience, behavioral state at the time of exposure, and indirect effects. Responses may be also

be influenced by other non-sound related factors (Ellison et al. 2011; Goldbogen et al. 2013; Kight and Swaddle 2011; McGregor 2013; Williams et al. 2014) (Read et al. 2014). McGregor (2013) summarized sound impacts and described two types of possible effects based on the studies they reviewed: 1) an apparent effect of noise on communication, but with a link between demonstrated proximate cost and ultimate cost in survival or reproductive success being inferred rather than demonstrated, and 2) studies showing a decrease in population density or diversity in relation to noise, but with a relationship that is usually a correlation, so factors other than noise or its effect on communication might account for the relationship. Within the ocean environment, aggregate anthropogenic impacts have to be considered in context of natural variation and climate change (Boyd and Hutchins 2012). These contexts can include additive effects from two or more factors, multiplicity where response from two or more factors is greater than the sum of individual effects, synergism between factors and response, antagonism as a negative feedback between factors, acclimation as a short-term individual response, and adaptation as a long-term population change (Boyd and Hutchins 2012). To address aggregate impacts and responses from any changes due to processes such as habituation, tolerance, and sensitization, future experiments over an extended period of time still need further research (Bejder et al. 2009; Blickley et al. 2012) (Read et al. 2014).

Some, including (Goldbogen et al. 2013) and (Stockin et al. 2008) have speculated that repeated interruptions of a marine mammal's normal activity could lead to fitness consequences and eventually, long-term implications for the population. However, to our knowledge, empirical data has not confirmed this to be the case. For example, Goldbogen et al. (2013) suggested that if a blue whale responded to MFA sonar by temporarily interrupting feeding behavior, this could have impacts on individual fitness and eventually, population health. However, for this to be true, we would have to assume that an individual whale could not compensate for this lost feeding opportunity by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no indication this is the case, particularly since unconsumed prey would still be available in the environment following the cessation of acoustic exposure.

If sound exposure were to be concentrated in a relatively small geographic area over a long period of time (e.g., days or weeks during major training exercises), it would be possible for individuals confined to a specific area to be exposed to acoustic stressors (e.g., MFA sonar) multiple times during a relatively short time period. However, we do not expect this to occur as we would expect individuals to move and avoid areas where exposures to acoustic stressors are at higher levels (e.g., greater than 120dB). For example, Goldbogen et al. (2013) indicated some horizontal displacement of deep foraging blue whales in response to simulated MFA sonar. Given these animal's mobility and large ranges, we would expect these individuals to temporaily select alternative foraging sites nearby until the exposure levels in their initially selected foraging area have decreased. Therefore, even temporary displacement from initially selected foraging habitat is not expected to impact the fitness of any individual animals because we would expect equivalent foraging to be available in close proximity. Because we do not expect any fitness consequences from any individual animals, we do not expect any population level effects from these behavioral responses.

6.2.12 Stranding

When a marine mammal swims or floats (live or dead) onto shore and becomes "beached" or incapable of returning to sea, the event is termed a "stranding" (Geraci et al. 1999; Geraci and Lounsbury 2005). Animals outside of their "normal" habitat are also sometimes considered "stranded" even though they may not have beached themselves. The legal definition for a stranding within the United States is that: (A) a marine mammal is dead and is (i) on a beach or shore of the United States; or (ii) in waters under the jurisdiction of the United States (including any navigable waters); or (B) a marine mammal is alive and is (i) on a beach or shore of the United States and is unable to return to the water; (ii) on a beach or shore of the United States and, although able to return to the water, is apparently in need of medical attention; or (iii) in the waters under the jurisdiction of the United States (including any navigable waters), but is unable to return to its natural habitat under its own power or without assistance" (16 United States Code Section 1421h).

Marine mammals are subjected to a variety of natural and anthropogenic factors, acting alone or in combination, which may cause a marine mammal to strand on land or die at-sea (Geraci et al. 1999; Geraci and Lounsbury 2005). Even for the fractions of more thoroughly investigated strandings involving post-stranding data collection and necropsies, the cause (or causes) for the majority of strandings remain undetermined. Natural factors related to strandings include the availability of food, predation, disease, parasitism, climatic influences, and aging (Bradshaw et al. 2006; Culik 2004; Geraci et al. 1999; Geraci and Lounsbury 2005; Hoelzel 2003; NRC 2003; Perrin and Geraci 2002; Walker et al. 2005). Anthropogenic factors include pollution (Anonmyous 2010; Elfes et al. 2010; Hall et al. 2006a; Hall et al. 2006b; Jepson et al. 2005; Tabuchi et al. 2006), vessel strike (Berman-Kowalewski et al. 2010; De Stephanis and Urquiola 2006; Geraci and Lounsbury 2005; Jensen and Silber 2003b; Laist et al. 2001), fisheries interactions (Look 2011; Read et al. 2006), entanglement (Baird and Gorgone 2005; Johnson et al. 2005; Saez et al. 2013), and noise (Cox et al. 2006; NRC 2003; Richardson et al. 1995c).

Along the coasts of the continental United States and Alaska between 2001 and 2009, there were approximately 1,400 cetacean strandings and 4,300 pinniped strandings (5,700 total) per year (NMFS 2011b; NMFS 2011c; NMFS 2011d). Several "mass stranding" events—strandings that involve two or more individuals of the same species (excluding a single cow-calf pair)—that have occurred over the past two decades have been associated with naval operations, seismic surveys, and other anthropogenic activities that introduced sound into the marine environment. An in-depth discussion of strandings is presented in DoN (2013b).

Sonar use during exercises involving U.S. Navy (most often in association with other nations' defense forces) has been identified as a contributing cause or factor in five specific mass stranding events: Greece in 1996; the Bahamas in March 2000; Madeira Island, Portugal in 2000; the Canary Islands in 2002, and Spain in 2006 (MMC 2006). These five mass stranding events have resulted in approximately 40 known stranding deaths among cetaceans, consisting mostly of beaked whales, with a potential link to sonar (ICES 2005a; ICES 2005b; ICES 2005c). The U.S.-Navy-funded research involving Behavioral Response Studies in SOCALand the Bahamas discussed previously were motivated by the desire to understand any links between the use of mid-frequency sonar and cetacean behavioral responses, including the potential for strandings. Although these events have served to focus attention on the issue of impacts resulting from the

use of sonar, as Ketten (2012) recently pointed out, "ironically, to date, there has been no demonstrable evidence of acute, traumatic, disruptive, or profound auditory damage in any marine mammal as the result [of] anthropogenic noise exposures, including sonar."

In these previous circumstances, exposure to non-impulsive acoustic energy has been considered a potential indirect cause of the death of marine mammals (Cox et al. 2006). One hypothesis regarding a potential cause of the strandings is tissue damage resulting from "gas and fat embolic syndrome" (Fernandez et al. 2005a; Jepson et al. 2003; Jepson et al. 2005). Models of nitrogen saturation in diving marine mammals have been used to suggest that altered dive behavior might result in the accumulation of nitrogen gas such that the potential for nitrogen bubble formation is increased (Houser 2010; Houser et al. 2001b; Zimmer and Tyack 2007). If so, this mechanism might explain the findings of gas and bubble emboli in stranded beaked whales. It is also possible that stranding is a behavioral response to a sound under certain contextual conditions and that the subsequently observed physiological effects (e.g., overheating, decomposition, or internal hemorrhaging from being on shore) were the result of the stranding rather than direct physical impact from exposure to sonar (Cox et al. 2006).

In May 2003 there was an incident involving the use of mid-frequency sonar by the USS SHOUP, which was portrayed in some media reports at the time as having potentially causing harbor porpoise strandings in the region. On May 5, 2003, in the area of Admiralty Inlet, the USS SHOUP began the use of mid-frequency sonar as part of a training event, which continued until later that afternoon and ended as the USS SHOUP transited Haro Strait heading north. Between May 2 and June 2, 2003, approximately 16 strandings involving 15 harbor porpoises (*Phocoena phocoena*) and 1 Dall's porpoise (*Phocoenoides dalli*) had been reported to the Northwest Marine Mammal Stranding Network, and allegations were made that these strandings had been caused by the USS SHOUP's use of sonar. A comprehensive review of all strandings and the events involving USS SHOUP on May 5, 2003, were subsequently presented in a report by U.S. Department of Navy (DON 2004).

Additionally NMFS undertook a series of necropsy analyses on the stranded animals to determine the cause of the strandings (NMFS 2005a; Norman et al. 2004a). Necropsies were performed on 10 of the porpoises and two heads were selected for computed tomographic imaging (Norman et al. 2004a).

None of the 11 harbor porpoises demonstrated signs of acoustic trauma. A putative cause of death was determined for five of the porpoises based only on the necropsy results; two animals had blunt trauma injuries and three animals had indication of disease processes. A cause of death could not be determined in the remaining animals, which is consistent with the expected percentage of marine mammal necropsies conducted within the northwest region. It is important to note, that these determinations were based only on the evidence from the necropsy to avoid bias with regard to determinations of the potential presence or absence of acoustic trauma. For example, the necropsy investigators had no knowledge of other potential external causal factors, such as Specimen 33NWR05005 having been found tangled in a fishing net, which may have otherwise assisted in their determination regarding the likely cause of death for that animal. Additionally, seven of the porpoises collected and analyzed died prior to SHOUP departing to sea on May 5, 2003. Of these seven, one, discovered on May 5, 2003, was in a state of moderate

decomposition, indicating it died before May 5; the cause of death was determined, most likely, to be Salmonella septicemia. Another porpoise, discovered at Port Angeles on May 6, 2003, was in a state of moderate decomposition, indicating that this porpoise also died prior to May 5. One stranded harbor porpoise discovered fresh on May 6 is the only animal that could potentially be linked to the USS SHOUP's May 5 active sonar use. Necropsy results for this porpoise found no evidence of acoustic trauma. The remaining eight strandings were discovered 1 to 3 weeks after the USS SHOUP's May 5 use of sonar. Two of the eight porpoises died from blunt trauma injury and a third suffered from parasitic infestation, which possibly contributed to its death (Norman et al. 2004a). For the remaining five porpoises, NMFS was unable to identify the causes of death.

NMFS concluded from a retrospective analysis of stranding events that the number of harbor porpoise stranding events in the approximate month surrounding the USS SHOUP's use of sonar was higher than expected based on annual strandings of harbor porpoises (Norman et al. 2004a). This conclusion in the NMFS report also conflicts with data from The Whale Museum, which has documented and responded to harbor porpoise strandings since 1980 (Osborne 2003). According to The Whale Museum, the number of strandings as of May 15, 2003, was consistent with what was expected based on historical stranding records and was less than that occurring in certain years. For example, since 1992, the San Juan Stranding Network has documented an average of 5.8 porpoise strandings per year. In 1997, there were 12 strandings in the San Juan Islands, with more than 30 strandings throughout the general Puget Sound area. In reporting their findings, NMFS acknowledged that the intense level of media attention to the 2003 strandings likely resulted in increased reporting effort by the public over that which is normally observed (Norman et al. 2004a). NMFS also noted in its report that the "sample size is too small and biased to infer a specific relationship with respect to sonar usage and subsequent strandings." It was also clear that in 2003, the number of strandings from May to June was also higher for the outer coast, indicating a much wider phenomena than use of sonar by USS SHOUP in Puget Sound for one day in May. It was later determined by NMFS that the number of harbor porpoise strandings in the northwest had been increased beginning in 2003 and through 2006. On November 3, 2006, an Unusual Mortality Event in the Pacific Northwest was declared by NMFS (see (DoN 2013b), Cetacean Stranding Report for more detail on this Unusual Mortality Event).

The speculative association of the harbor porpoise strandings to the use of sonar by the USS SHOUP was inconsistent with prior stranding events linked to the use of mid-frequency sonar. Specifically, in prior events strandings occurred shortly after the use of sonar (less than 36 hours) and stranded individuals were spatially co-located. Although MFA sonar was used by the USS SHOUP, the distribution of harbor porpoise strandings by location and with respect to time surrounding the event do not support the suggestion that MFA sonar was a cause of harbor porpoise strandings. Rather, a lack of evidence of any acoustic trauma within the harbor porpoises, and the identification of probable causes of stranding or death in several animals, supports the conclusion that harbor porpoise strandings in 2003 in the Pacific Northwest were unrelated to the sonar activities by the USS SHOUP.

As the ICES (2005c) noted, taken in context of marine mammal populations in general, sonar is not a major threat, or significant portion of the overall ocean noise budget. This has also been demonstrated by monitoring in areas where the Navy operates (Bassett et al. 2010; Baumann-Pickering et al. 2010; Hildebrand et al. 2011; McDonald et al. 2006a; Tyack et al. 2011a).

Regardless of the direct cause, the Navy considers potential sonar related strandings important and continues to fund research and work with scientists to better understand circumstances that may result in strandings. During a Navy training event on March 4, 2011, at the Silver Strand Training Complex in San Diego, California, four long-beaked common dolphins were killed by the detonation of an underwater explosive (Danil and St. Leger 2011). This area has been used for underwater demolitions training for at least 3 decades without incident. During this underwater detonation training event, a pod of 100 to 150 long-beaked common dolphins were moving towards the explosive's 700-yd. (640 m) exclusion zone monitored by a personnel in a safety boat and participants in a dive boat. Within the exclusion zone, approximately 5 minutes remained on a time-delayed firing device connected to a single 8.76 lb (3.8 kg) explosive charge set at a depth of 48 ft. (14.6 m), approximately 0.5 to 0.75 nm from shore. Although the dive boat was placed between the pod and the explosive in an effort to guide the dolphins away from the area, that effort was unsuccessful and three long-beaked common dolphins died as a result of being in proximity to the explosion. In addition, to the three dolphins found dead on March 4th at the event site, the remains of a fourth dolphin were discovered on March 7th (3 days later and approximately 42 mi. (68 km) from the location where the training event occurred), which was assessed as being related to this event (Danil and St. Leger 2011). Details such as the dolphins' depth and distance from the explosive at the time of the detonation could not be estimated from the 250-yd (229 m) standoff point of the observers in the dive boat or the safety boat.

These dolphin mortalities are the only known occurrence of a U.S. Navy training event involving impulsive energy (underwater detonation) that has resulted in injury to a marine mammal. Despite this being a rare occurrence, the Navy has reviewed training requirements, safety procedures, and potential mitigation measures and, along with NMFS, is determining appropriate changes to reduce the potential for this to occur in the future.

In comparison to potential strandings or injury resulting from events associated with Navy activities, marine mammal strandings and injury from commercial vessel ship strike (Berman-Kowalewski et al. 2010; Silber et al. 2010), impacts from urban pollution (Hooker et al. 2007; O'Shea and Brownell Jr. 1994), and annual fishery-related entanglement, bycatch, injury, and mortality (Baird and Gorgone 2005; Forney and Kobayashi 2007; Saez et al. 2013), have been estimated worldwide to be orders of magnitude greater (hundreds of thousands of animals versus tens of animals; (Culik 2004; ICES 2005c; Read et al. 2006)) than the few potential injurious impacts that could be possible as a result of Navy activities. This does not negate the potential influence of mortality or additional stress to small, regionalized sub-populations which may be at greater risk from human related mortalities (fishing, vessel strike, sound) than populations with larger oceanic level distributions, but overall the Navy's impact in the oceans and inland water areas where training occurs is small by comparison to other human activities. Nonetheless, the focus of our analysis is to determine, considering the status of the resources, the environmental baseline and effects from future non-federal activities, whether the Navy's activities are likely to jeopardize listed species or are likely to destroy or adversely modify critical habitat.

6.2.13 Long-term Consequences to the Individual and the Population

Long-term consequences to a population are determined by examining changes in the population growth rate. Individual effects that could lead to a reduction in the population growth rate include mortality or injury (that removes animals from the reproductive pool), hearing loss (which

depending on severity could impact navigation, foraging, predator avoidance, or communication), chronic stress (which could make individuals more susceptible to disease), displacement of individuals (especially from preferred foraging or mating grounds), and disruption of social bonds (due to masking of conspecific signals or displacement). However, the long-term consequences of any of these effects are difficult to predict because individual experience and time can create complex contingencies, especially for intelligent, long-lived animals like marine mammals. While a lost reproductive opportunity could be a measureable cost to the individual, the outcome for the animal, and ultimately the population, can range from insignificant to significant. Any number of factors, such as maternal inexperience, years of poor food supply, or predator pressure, could produce a cost of a lost reproductive opportunity, but these events may be "made up" during the life of a normal healthy individual. The same holds true for exposure to human-generated noise sources. These biological realities must be taken into consideration when assessing risk, uncertainties about that risk, and the feasibility of preventing or recouping such risks. The long-term consequence of relatively trivial events like short-term masking of a conspecific's social sounds, or a single lost feeding opportunity, can be exaggerated beyond its actual importance by focusing on the single event and not the important variable, which is the individual and its lifetime parameters of growth, reproduction and survival.

Population models are well known from many fields in biology including fisheries and wildlife management. These models accept inputs for the population size and changes in vital rates of the population such as the mean values for survival age, lifetime reproductive success, and recruitment of new individuals into the population. The time-scale of the inputs in a population model for long-lived animals such as marine mammals is on the order of seasons, years, or life stages (e.g., neonate, juvenile, reproductive adult), and are often concerned only with the success of individuals from one time period or stage to the next. Unfortunately, information is not available to accurately assess the impact of acoustic and explosive exposure on individual marine mammal vitals rates. Further for assessing the impact of acoustic and explosive impacts to marine mammal populations, many of the inputs required by population models are not known.

Recently, efforts have been made to understand the linkage between a stressor, such as anthropogenic sound, and its immediate behavioral or physiological consequences for the individual, and then the subsequent effects on that individual's vital rates (growth, survival and reproduction), and the consequences, in turn, for the population. In 2005, a panel convened by the National Research Council of the United States National Academy of Sciences published a report on 'Marine Mammal Populations and Ocean Noise: Determining When Noise Causes Biologically Significant Effects'. The panel developed what it called "a conceptual model" that outlined how marine mammals might be affected by anthropogenic noise and how population level effects could be inferred on the basis of observed behavioral changes. They called this model 'Population Consequences of Acoustic Disturbance' (PCAD). In 2009 the US Office of Naval Research (ONR) set up a working group to transform this framework into a formal mathematical structure and determine how that structure could be parameterized using data from a number of case studies. The ONR working group extended the PCAD framework so that it could be used to consider other forms of disturbance and to address the impact of disturbance on physiology as well as behavior. Their current version of that framework is now known as PCoD (Population Consequences of Disturbance) (New et al. 2014). It is important to note that PCoD is

ongoing and is an exploratory project to determine how an interim PCoD approach might inform analysis. It is not intended to provide an actual assessment of the population-level consequences of disturbance for beaked whale populations on Navy ranges.

New et al. (2013) developed a mathematical model simulating a functional link between feeding energetics and a species' requirements for survival and reproductions for 21 species of beaked whale. The authors report "reasonable confidence" in their model, although approximately 29 percent (6 of 21 beaked whale species modeled) failed to survive or reproduce, which the authors attribute to possible inaccuracies in the underlying parameters. Based on the model simulation, New et al. (2013) determined that if habitat quality and "accessible energy" (derived from the availability of either plentiful prey or prey with high energy content) are both high, then survival rates are high as well. If these variables are low, then adults may survive but calves will not. For the 29 percent of beaked whale species for which the model failed (within the assumed range of current inputs), the assumption was a 2-year calving period (or inter-calf interval), however, for species with longer gestation periods (such as the 17-month gestation period of Baird's beaked whale (Berardius bairdii), this inter-calf interval may be too short. For Blainville's beaked whale, (Claridge 2013) has shown that calf age at separation is at least 3 years, and that the inter-calf interval at Abaco in the Bahamas may be 4 years. New et al. (2013) acknowledge that an assumed 2-year calving period in the modeling may not be long enough to build up the energetic resources necessary for mother and calf survival.

As another critical model assumption, prey preferences were modeled based on stomach content analyses of stranded animals, which the authors acknowledge are traditionally poor estimates of the diets of healthy animals, as stranded animals are often sick prior to stranding. Stomach content remnants of prey species do not digest equally, as only the hard parts of some prey types remain (e.g., fish otoliths, beaks of cephalopods) and thus often provide an incomplete picture of diet. Given these unknowns and the failure of the simulation to work for 29 percent of beaked whale species, the modeled survival rates of all beaked whales, particularly those modeled with prey having low energy content, may be better than simulated if higher-energy prey makes up a larger part of the diet than assumed by the model simulations.

In short, for the model output New et al. (2013) created to correctly represent links between the species and their environment, that model must identify all the critical and relevant ecological parameters as input variables, provide the correct values for those parameters, and then the model must appropriately integrate modeling functions to duplicate the complex relationships the model intends to represent. If an assumption (model input) such as calving period or prey preferences is incorrect (and there is presently no way to know), then the model would not be representing what may actually be occurring. New et al. (2013) report that their simulations suggest that adults will survive but not reproduce if anthropogenic disturbances result in being displaced to areas of "impaired foraging." Underlying this suggestion is the additional unstated assumption that habitat capable of sustaining a beaked whale is limited in proximity to where any disturbance has occurred and there are no data to indicate that is a valid assumption.

While the New et al. (2013) model provides a test case for future research, this pilot study has very little of the critical data necessary to form any conclusions applicable to current management decisions. The authors note the need for more data on prey species and reproductive

parameters including gestation and lactation duration, as the model results are particularly affected by these assumptions. Therefore, any suggestion of biological sensitivity to the simulation's input parameters is uncertain.

New et al. (2014) used a simulation model to assess how behavioral disruptions (e.g., significant disruption of foraging behavior) may affect southern elephant seal health, offspring survival, individual fitness, and population growth rate. They suggested their model can determine the population consequences of disturbance from short-term changes in individual animals. Their model assumed that disturbance affected behavior by reducing the number of drift dives in which the animals were feeding and increasing the time they spent in transit. For example, they suggested a disturbance lasting 50 percent of an average annual foraging trip would reduce pup survival by 0.4 percent. If this level of disturbance continued over 30 years and the population did not adapt, the authors found that the population size would decrease by approximately 10 percent.

The findings of New et al. (2014) are not applicable to the temporary behavioral disruptions that may be caused by Navy training and testing activities for a number of reasons. First, the model assumed that individuals would be unable to compensate for lost foraging opportunities. As described previously, available empirical data does not confirm this would be the case. For example, elephant seals are unlikely to be affected by short-term variations in prey availability because they take long foraging trips, allowing for some margin of error in prey availability (Costa 1993), as cited in New et al. (2014). We expect the species considered in this Opinion to be similarly unaffected. We have no information to suggest animals eliciting a behavioral response (e.g., temporary disruption of feeding) to Navy training and testing activities would be unable to compensate for this temporary disruption in feeding activity by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. Additionally, the behavioral disruption of ESA-listed species reasonably expected to occur due to Navy training and testing activities will not have as long of a duration as those considered in the New et al. (2014) study. As discussed in Section 6.2.11, no individual animals will be exposed to Navy training and testing activities for a long enough duration to disrupt 50 percent of its annual feeding opportunities over multiple years. New et al. (2014) suggest it would be unlikely even for episodic environmental change, such as El Niño events, to affect the probability of population persistence. As suggested by the authors, the New et al. (2014) model may be more applicable to the consideration of potential long-term behavioral disruptions (e.g., those that may result from climate change).

Until an appropriate quantitative model is developed and until all relevent empirical data is collected to support such a model for the species considered in this Opinion, the best assessment of long-term consequences from training and testing activities will be to monitor the populations over time within a given Navy range complex. A U.S. Navy workshop on Marine Mammals and Sound (Fitch et al. 2011) indicated a critical need for baseline biological data on marine mammal abundance, distribution, habitat, and behavior over sufficient time and space to evaluate impacts from human-generated activities on long-term population survival. The Navy has developed monitoring plans for protected marine mammals and sea turtles occurring on Navy ranges with the goal of assessing the impacts of training activities on marine species and the effectiveness of the Navy's current mitigation practices. Monitoring has resulted in data on occurrence, exposure,

and behavioral response in the MITT Action Area. All monitoring reported are available to the public and posted at www.navymarinespeciesmonitoring.us/.

6.2.14 Criteria for Predicting Acoustic and Explosive Impacts – Marine Mammals

When Navy activities introduce sound or explosive energy into the marine environment, an analysis of potential impacts to marine mammals is conducted. To do this, information about the numerical sound and energy levels that are likely to elicit certain types of physiological and behavioral reactions is needed. The following contains information on the Navy's criteria, thresholds, and methodology for quantifying impacts from acoustic and explosive sources, which were jointly developed with NMFS. For this information in its entirety, please see Navy 2013.

6.2.14.1 *Frequency Weighting*

Frequency-weighting functions are used to adjust the received sound level based on the sensitivity of the animal to the frequency of the sound. The weighting functions de-emphasize sound exposures at frequencies to which marine mammals are not particularly sensitive. This effectively makes the acoustic thresholds frequency-dependent, which means they are applicable over a wide range of frequencies and therefore applicable for a wide range of sound sources. Frequency-weighting functions, called "M-weighting" functions, were proposed by Southall et al. (2007b) to account for the frequency bandwidth of hearing in marine mammals. These M-weighting functions were derived for each marine mammal hearing group based on an algorithm using the range of frequencies that are within 80 kHz of an animal or group's best hearing. The Southall et al. (2007b) M-weighting functions are nearly flat between the lower and upper cutoff frequencies, and thus were believed to represent a conservative approach to assessing the effects of noise (Figure 21). For the purposes of this analysis, we refer to these as Type I auditory weighting functions. Otariid seal thresholds and weighting functions were applied to sea otter as described in Finneran and Jenkins (2012).

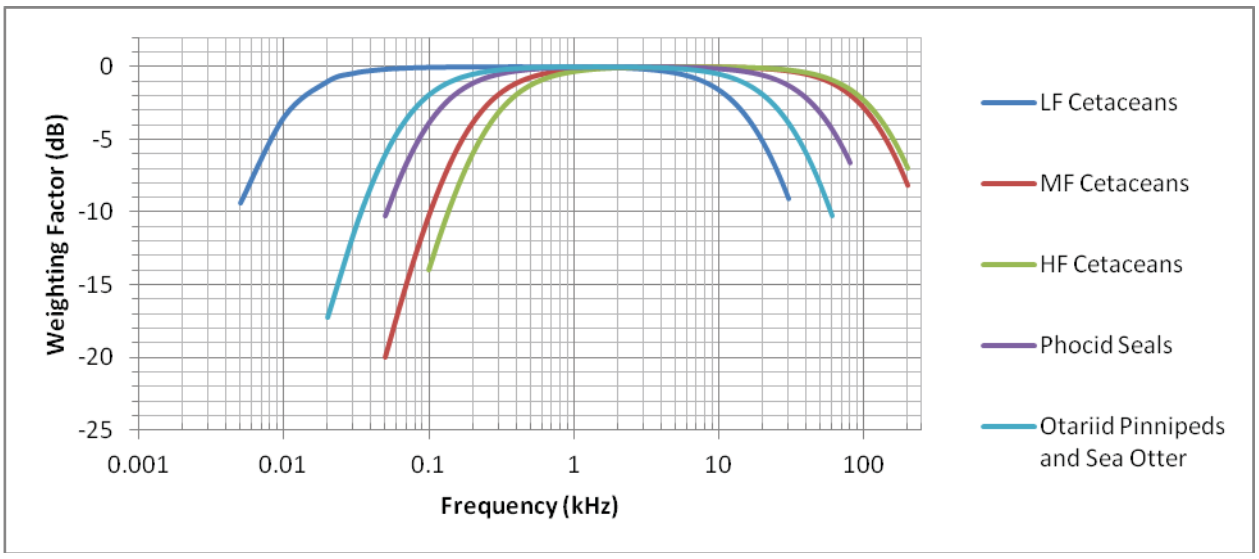

Figure 21. Type I Auditory Weighting Functions Modified from the Southall et al. (2007) M-Weighting Functions

Finneran and Jenkins (2012) considered data since Southall et al. (2007b) and determined two published studies suggested adjustments to the weighting functions were appropriate. The first experiment measured TTS in a bottlenose dolphin after exposure to pure tones with frequencies from 3 to 28 kHz (Finneran and Schlundt 2010). These data were used to derive onset-TTS values as a function of exposure frequency, and demonstrate that the use of a single numeric threshold for onset-TTS, regardless of frequency, is not correct. The second experiment examined how subjects perceived the loudness of sounds at different frequencies to derive equal loudness contours (Finneran and Schlundt 2011a). These data are important because human auditory weighting functions are based on equal loudness contours. The dolphin equal loudness contours provide a means to generate auditory weighting functions in a manner directly analogous to the approach used to develop safe exposure guidelines for people working in noisy environments (NIOSH 1998).

Taken together, the recent higher-frequency TTS data and equal loudness contours provide the underlying data necessary to develop new weighting functions, referred to as Type II auditory weighting functions. Type II auditory weighting functions improve accuracy and avoid underestimating the impacts to animals at higher frequencies as shown in Figure 22. To generate the new Type II weighting functions, Finneran and Schlundt (2011b) substituted lower and upper frequency values which differ from the values used by Southall et al. (2007b).

The new weighting curve predicts appreciably higher (almost 20 dB) susceptibility for frequencies above 3 kHz for bottlenose dolphins, a mid-frequency cetacean. Since data below 3 kHz are not available, the original weighting functions from Southall et al. (2007b) were substituted below this frequency. Low- and high-frequency cetacean weighting functions were extrapolated from the dolphin data as well, because of the suspected similarities of greatest susceptibility at best frequencies of hearing. Similar Type II weighting curves were not developed for pinnipeds since their hearing is markedly different from cetaceans, and because they do not hear as well at higher frequencies. Their weighting curves do not require the same adjustment (see Finneran and Jenkins (2012) for additional details).

The Type II auditory cetacean weighting functions (Figure 22) are applied to the received sound level before comparing it to the appropriate sound exposure level thresholds for TTS or PTS, or the impulse behavioral response threshold. Note that for pinnipeds and sea otters, the Southall et al. (2007) weighting functions (Figure 22) are used in lieu of any new weighting functions. For some criteria, received levels are not weighted before being compared to the thresholds to predict effects. These include the peak pressure criteria for predicting TTS and PTS from underwater explosions, the acoustic impulse metrics used to predict onset-mortality and slight lung injury, and the thresholds used to predict behavioral responses from harbor porpoises and beaked whales from sonar and other active acoustic sources.

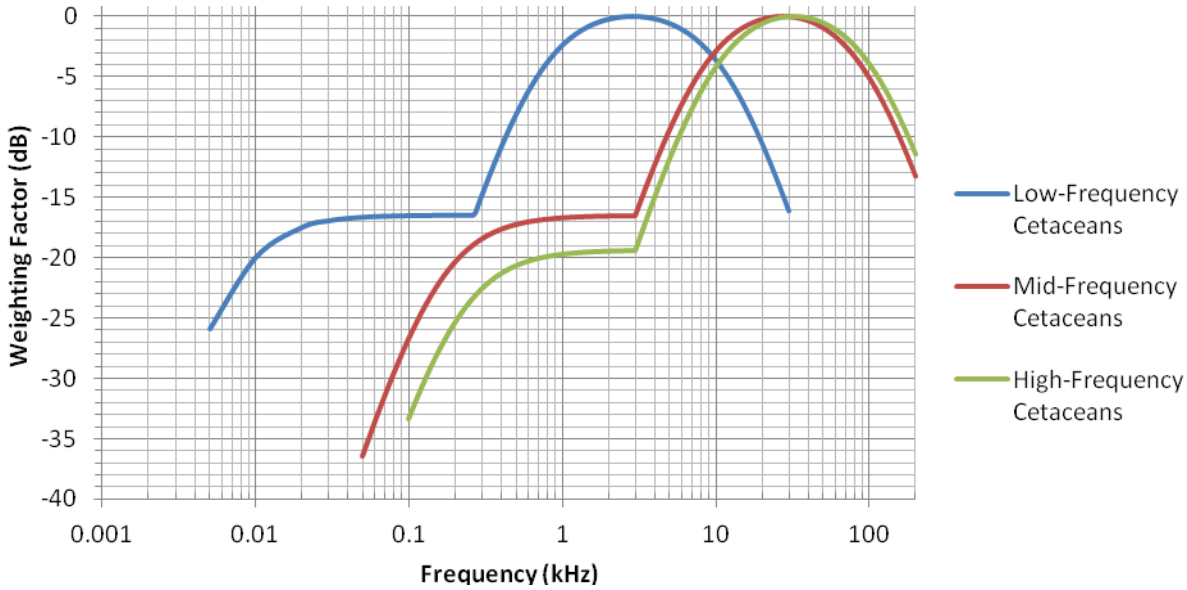

Figure 22. Type II Weighting Functions for Low-, Mid-, and High-Frequency Cetaceans

6.2.14.2 ***Summation of Energy from Multiple Sources***

In most cases, an animal's received level will be the result of exposure to a single sound source. In some scenarios, however, multiple sources will be operating simultaneously, or nearly so, creating the potential for accumulation of energy from multiple sources. Energy is summed for multiple exposures of similar source types. For sonar, including use of multiple systems within any scenario, energy will be summed for all exposures within a cumulative exposure band, with the cumulative exposure bands defined in four bands: 0 to 1.0 kHz (low-frequency sources), 1.1 to 10.0 kHz (mid-frequency sources), 10.1 kHz to 100.0 kHz (high-frequency sources), and above 100.0 kHz (very high-frequency sources). Sources operated at frequencies above 200 kHz are considered to be inaudible to all groups of marine mammals and are not analyzed in the quantitative modeling of exposure levels. After the energy has been summed within each frequency band, the band with the greatest amount of energy is used to evaluate the onset of PTS or TTS. For explosives, including use of multiple explosives in a single scenario, energy is summed across the entire frequency band.

6.2.14.3 ***Hearing Loss – Temporary and Permanent Threshold Shift***

Criteria for physiological effects (Table 35) from sonar and other active acoustic sources are based on TTS and PTS with thresholds based on cumulative sound exposure levels. The onset of TTS or PTS from exposure to impulsive sources is predicted using a sound exposure level-based threshold in conjunction with a peak pressure threshold. The horizontal ranges are then compared, with the threshold producing the longest range being the one used to predict effects. For multiple exposures within any 24-hour period, the received sound exposure level for individual events is accumulated for each animal. Since no studies have been designed to intentionally induce PTS in marine mammals, onset-PTS levels have been estimated using empirical TTS data obtained from marine mammals and relationships between TTS and PTS established in terrestrial mammals.

Temporary and permanent threshold shift thresholds are based on TTS onset values for impulsive and non-impulsive sounds obtained from representative species of mid- and high-frequency cetaceans and pinnipeds. These data are then extended to the other marine mammals for which data are not available. The *Criteria and Thresholds for U.S. Navy Acoustic and Explosive Effects Analysis Technical Report* provides a detailed explanation of the selection of criteria and derivation of thresholds for temporary and permanent hearing loss for marine mammals (Finneran and Jenkins 2012).

Table 35. Acoustic Criteria and Thresholds for Predicting Physiological Effects to Marine Mammals Underwater from Sonar and Other Active Acoustic Sources

Hearing Group	Species	Onset temporary	Onset permanent
Low-Frequency Cetaceans	All mysticetes	178 dB re 1 µPa^2-s SEL (Type II weighting)	198 dB re 1 µPa^2-s SEL (Type II weighting)
Mid-Frequency Cetaceans	Dolphins, beaked whales, and medium and large toothed whales	178 dB re 1 µPa^2-s SEL (Type II weighting)	198 dB re 1 µPa^2-s SEL (Type II weighting)
High-Frequency Cetaceans	Porpoises and *Kogia* spp.	152 dB re 1 µPa^2-s SEL (Type II weighting)	172 dB re 1 µPa^2-s SEL (Type II weighting)
Phocid Seals (underwater)	Northern Elephant & Harbor Seals	183 dB re 1 µPa^2-s SEL (Type I weighting)	197 dB re 1 µPa^2-s SEL (Type I weighting)
Otariidae (underwater)	Sea Lion & Fur Seals	206 dB re 1 µPa^2-s SEL (Type I weighting)	220 dB re 1 µPa^2-s SEL (Type I weighting)
Mustelidae (underwater)	Sea Otters		

Notes: dB = decibels, SEL = Sound Exposure Level, dB re 1 µPa^2-s = decibels referenced to 1 micropascal squared second

6.2.14.3.1 Temporary Threshold Shift – Non-Impulsive Sources

Temporary threshold shift involves no tissue damage, is by definition temporary, and therefore is not considered injury. The onset of TTS in mid-frequency cetaceans exposed to non-impulsive sound are derived from multiple studies (Finneran et al. 2010; Finneran et al. 2005b; Finneran and Schlundt 2010; Mooney 2009; Schlundt et al. 2000) from two species, bottlenose dolphins and beluga whales. Especially notable are data for frequencies above 3 kHz, where bottlenose dolphins have exhibited lower TTS onset thresholds than at 3 kHz (Finneran 2011; Finneran and Schlundt 2010). This difference in TTS onset at higher frequencies is incorporated into the weighting functions.

Lucke et al. (2009) measured TTS in a harbor porpoise exposed to a small seismic air gun and those results are reflected in the current impulsive sound TTS thresholds described below. The beluga whale, which had been the only species for which both impulsive and non-impulsive TTS data exist, has a non-impulsive TTS onset value about 6 dB above the (weighted) impulsive threshold (Finneran et al. 2002; Schlundt et al. 2000). Therefore, 6 dB was added to the harbor porpoise's impulsive TTS threshold demonstrated by Lucke et al. (2009) to derive the non-impulsive TTS threshold used in the current Navy modeling for high frequency cetaceans. The first direct measurements of TTS from non-impulsive sound was presented by Kastelein et al. (2012d) for harbor porpoise. These data are fully consistent with the current harbor porpoise thresholds used in the modeling of effects from non-impulsive sources.

There are no direct measurements of TTS or hearing abilities for low-frequency cetaceans. The Navy uses mid-frequency cetacean thresholds to assess PTS and TTS for low-frequency cetaceans, since mid-frequency cetaceans are the most similar to the low frequency group (see Finneran and Jenkins (2012) on the development of the thresholds and criteria).

Pinniped TTS criteria are based on data provided by Kastak et al. (2005) for representative species of both of the pinniped hearing groups: harbor seals (Phocidae) and California sea lions (Otariidae). Kastak et al. (2005) used octave band noise centered at 2.5 kHz to extrapolate an onset TTS threshold. More recently Kastelein et al. (2012a) used octave band noise centered at 4 kHz to obtain TTS thresholds in the same two species resulting in similar levels causing onset-TTS as those found in Kastak et al. (2005). For sea otters, the otariid TTS threshold and weighting function are applied due to similarities in taxonomy and auditory performance. The appropriate frequency weighting function for each species group is applied when using the sound exposure level-based thresholds to predict TTS.

Table 36 illustrates the ranges to the onset of TTS (i.e., the maximum distances to which TTS would be expected) for one, five, and ten pings from four representative source bins and sonar systems. Due to the lower acoustic thresholds for TTS versus PTS, ranges to TTS are longer; this can also be thought of as a larger volume acoustic footprint for TTS effects. Because the effects threshold is total summed sound energy and because of the longer distances, successive pings can add together, further increasing the range to onset-TTS.

Table 36. Approximate Maximum Ranges to the Onset of Temporary Threshold Shift for Four Representative Sonar Over a Representative Range of Ocean Environments

Functional Hearing Group	Approximate Ranges to the Onset of TTS (meters)											
	Sonar Bin MF1 (e.g., SQS-53; ASW Hull-Mounted Sonar)			Sonar Bin MF4 (e.g., AQS-22; ASW Dipping Sonar)			Sonar Bin MF5 (e.g., SSQ-62; ASW Sonobuoy)			Sonar Bin HF4 (e.g., SQQ-32; MIW Sonar)		
	One Ping	Five Pings	Ten Pings	One Ping	Five Pings	Ten Pings	One Ping	Five Pings	Ten Pings	One Ping	Five Pings	Ten Pings
Low-frequency cetaceans	560-2,280	1,230-6,250	1,620-8,860	220-240	490-1,910	750-2,700	110-120	240-310	340-1,560	100-160	150-730	150-820

Functional Hearing Group	Approximate Ranges to the Onset of TTS (meters)											
	Sonar Bin MF1 (e.g., SQS-53; ASW Hull-Mounted Sonar)			Sonar Bin MF4 (e.g., AQS-22; ASW Dipping Sonar)			Sonar Bin MF5 (e.g., SSQ-62; ASW Sonobuoy)			Sonar Bin HF4 (e.g., SQQ-32; MIW Sonar)		
	One Ping	Five Pings	Ten Pings	One Ping	Five Pings	Ten Pings	One Ping	Five Pings	Ten Pings	One Ping	Five Pings	Ten Pings
Mid-frequency cetaceans	150-180	340-440	510-1,750	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50
High-frequency cetaceans	2,170-7,570	4,050-15,350	5,430-19,500	90	180-190	260-950	< 50	< 50	< 50	< 50	< 50	< 50
Otariid seals, sea lion, & Mustelid (sea otter)	230-570	1,240-1,300	1,760-1,780	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50	< 50
Phocid seals & Manatees	70-	200-	350-	< 50	100	150	< 50	< 50	< 50	< 50	< 50	< 50

6.2.14.3.2 Temporary Threshold Shift – Impulsive Sources

The TTS sound exposure level thresholds for cetaceans are consistent with the USS MESA VERDE ship shock trial that was approved by NMFS (73 FR 143) and are more representative of TTS induced from impulses (Finneran et al. 2002) rather than pure tones (Schlundt et al. 2000). In most cases, a total weighted sound exposure level is more conservative than greatest sound exposure level in one-third octave bands, which was used prior to the USS MESA VERDE ship shock trials. There are no data on TTS obtained directly from low-frequency cetaceans, so mid-frequency cetacean impulse threshold criteria from Finneran et al. (2002) have been used. High frequency cetacean TTS thresholds are based on research by Lucke et al. (2009), who exposed harbor porpoises to pulses from a single air gun.

Pinniped criteria were not included for prior ship shock trials, as pinnipeds were not expected to occur at the shock trial sites, and TTS criteria for previous Navy EIS/OEISs did not differentiate between cetaceans and pinnipeds (NMFS 2008b; NMFS 2008d). TTS values for impulse sound criteria have not been obtained for pinnipeds, but there are TTS data for octave band sound from representative species of both major pinniped hearing groups (Kastak et al. 2005). Impulsive sound TTS criteria for pinnipeds were estimated by applying the difference between mid-frequency cetacean TTS onset for impulsive and non-impulsive sounds to the pinniped non-impulsive TTS data (Kastak et al. 2005), a methodology originally developed by Southall et al. (Southall et al. 2007b). Therefore, the TTS criteria for impulsive sounds from explosions for pinnipeds is 6 dB less than the non-impulsive onset-TTS criteria derived from Kastak et al. (2005).

6.2.14.3.3 Permanent Threshold Shift – Non-Impulsive Sources

There are no direct measurements of PTS onset in marine mammals. Well understood relationships between terrestrial mammalian TTS and PTS have been applied to marine mammals. Threshold shifts up to 40 to 50 dB have been induced in terrestrial mammals without

resultant PTS (Miller et al. 1963; Ward et al. 1958; Ward et al. 1959a; Ward et al. 1959b). These data would suggest that a PTS criteria of 40 dB would be reasonable for conservatively predicting (overestimating) PTS in marine mammals. Data from terrestrial mammal testing (Ward et al. 1958; Ward et al. 1959a; Ward et al. 1959b) show growth of TTS by 1.5 to 1.6 dB for every 1 dB increase in exposure level. The difference between measureable TTS onset (6 dB) and the selected 40 dB upper safe limit of TTS yields a difference in TTS of 34 dB which, when divided by a TTS growth function of 1.6 indicates that an increase in exposure of 21 dB would result in 40 dB of TTS. For simplicity and additional conservatism we have rounded that number down to 20 dB (Southall et al. 2007b).

Therefore, exposures to sonar and other active acoustic sources with levels 20 dB above those producing TTS are assumed to produce a PTS. For example, an onset-TTS criteria of 195 dB re 1 μPa^2-s would have a corresponding onset-PTS criteria of 215 dB re 1 μPa^2-s. This extrapolation process is identical to that recently proposed by Southall et al. (Southall et al. 2007b). The method overestimates or predicts greater effects than have actually been observed in tests on a bottlenose dolphin (Finneran and Schlundt 2010; Schlundt et al. 2006) and is therefore protective.

Kastak et al. (2007) obtained different TTS growth rates for pinnipeds than Finneran and colleagues obtained for mid-frequency cetaceans. NMFS recommended reducing the estimated PTS criteria for both groups of pinnipeds, based on the difference in TTS growth rate reported by Kastak et al. (2007) (14 dB instead of 20 dB).

The appropriate frequency weighting function for each species group is applied when using the sound exposure level-based thresholds to predict PTS.

Table 37 lists the ranges to the PTS threshold (i.e., range to the onset of PTS: the maximum distance to which PTS would be expected), relative to the marine mammal's functional hearing group, from three of the most powerful sonar systems. For a SQS-53 sonar transmitting for 1 second at 3 kHz and a representative source level of 235 dB re 1 μPa^2-s at 1 m, the range to PTS for the most sensitive species (the high-frequency cetaceans) extends from the source to a range of 100 m (110 yd.). Since any hull mounted sonar, such as the SQS-53, engaged in anti-submarine warfare training would be moving at 10 to 15 knots (5.1 to 7.7 m/second) and nominally pinging every 50 seconds, the vessel will have traveled a minimum distance of approximately 260 m (280 yd) during the time between those pings (10 knots is the speed used in the Navy Acoustic Effects Model). As a result, there is little overlap of PTS footprints from successive pings, indicating that in most cases, an animal predicted to receive PTS would do so from a single exposure (i.e., one ping). For all other functional hearing groups (low-frequency cetaceans, mid-frequency cetaceans, and phocid seals and manatees) single-ping PTS zones are within 100 m of the sound source. A scenario could occur where an animal does not leave the vicinity of a ship or travels a course parallel to the ship within the PTS zone; however, the distances required make PTS exposure less likely. For a Navy vessel moving at a nominal 10 knots, it is unlikely a marine mammal could maintain the speed to parallel the ship and receive adequate energy over successive pings to suffer PTS. For all sources except hull-mounted sonar

(e.g., SQS-53 and BQQ-10) ranges to PTS are well within 50 m (55 yd), even for multiple pings (up to five pings) and the most sensitive functional hearing group (high-frequency cetaceans).

Table 37. Approximate Ranges to Permanent Threshold Shift Criteria for Each Functional Hearing Group for a Single Ping from Three of the Most Powerful Sonar Systems within Representative Ocean Acoustic Environments

Functional Hearing Group	Ranges to the Onset of PTS for One Ping (meters)		
	Sonar Bin MF1 (e.g., SQS-53; Anti-Submarine Warfare Hull Mounted Sonar)	Sonar Bin MF4 (e.g., AQS-22; Anti-Submarine Warfare Dipping Sonar)	Sonar Bin MF5 (e.g., SSQ-62; Anti-Submarine Warfare Sonobuoy)
Low-Frequency Cetaceans	70	10	<2
Mid-Frequency Cetaceans	10	<2	<2
High-Frequency Cetaceans	100	20	10
Phocid Seals	80	10	<2
Otariid Seals & Sea Lion, & Mustelid (Sea Otter)	10	<2	<2

6.2.14.3.4 Permanent Threshold Shift – Impulsive Sources

Since marine mammal PTS data from impulsive exposures do not exist, onset PTS levels for these animals are estimated by adding 15 dB to the sound exposure level-based TTS threshold and by adding 6 dB to the peak pressure based thresholds. These relationships were derived by Southall et al. (Southall et al. 2007b) from impulsive noise TTS growth rates in chinchillas. The appropriate frequency weighting function for each species group is applied when using the resulting sound exposure level-based thresholds, as shown in Figure 22, to predict PTS.Mortality and Injury from Explosives

There is a considerable body of laboratory data on actual injury for impulse sound, usually from explosive pulses, obtained from tests with a variety of lab animals (mice, rats, dogs, pigs, sheep, and other species). Onset Slight Gastrointestinal (GI) Tract Injury, Onset Slight Lung Injury, and Onset Mortality (a 50 percent lung injury with mortality occurring in 1 percent of those having this injury) represent a series of effects with increasing likelihood of serious injury or lethality. Primary impulse injuries from explosive blasts are the result of differential compression and rapid re-expansion of adjacent tissues of different acoustic properties (e.g., between gas-filled and fluid-filled tissues or between bone and soft tissues). These injuries usually manifest themselves in the gas-containing organs (lung and gut) and auditory structures (e.g., rupture of the eardrum across the gas-filled spaces of the outer and inner ear) (Craig and Hearn 1998) (Craig Jr. 2001a).

Criteria and thresholds for predicting injury and mortality to marine mammals from explosive sources are listed in Table 38. Upper and lower frequency limits of hearing are not applied for

lethal and injurious exposures. These criteria and their origins are explained in greater detail in Finneran and Jenkins (2012), who covered the development of the thresholds and criteria for assessment of impacts.

Table 38. Criteria and Thresholds for Predicting Physiological Effects to Marine Mammals Underwater for Explosives

Group	Species	Onset TTS	Onset PTS	Onset Slight GI Tract Injury	Onset Slight Lung Injury	Onset Mortality
Low-Frequency Cetaceans	Mysticetes	172 dB re 1 μPa^2-s (low-freq weighting) or 224 dB Peak SPL	187 dB re 1 μPa^2-s (low-freq weighting) or 230 dB Peak SPL	237 dB re 1 µPa	Equation 1	Equation 2
Mid-Frequency Cetaceans	Odontocetes (Toothed Whales)	172 dB re 1 μPa^2-s (mid-freq weighting) or 224 dB Peak SPL	187 dB re 1 μPa^2-s (mid-freq weighting) or 230 dB Peak SPL			
High-Frequency Cetaceans	Porpoises and *Kogia* spp.	146 dB re 1 μPa^2-s (mid-freq weighting) or 195 dB Peak SPL	161 dB re 1 μPa^2-s (mid-freq weighting) or 201 dB Peak SPL			
Phocid Seals (In-Water)	Harbor, beared, hooded common, spotted, ringed, harp, ribbon and gray seals	177 dB re 1 μPa^2-s (phocid weighting) or 212 dB Peak SPL	192 dB re 1 μPa^2-s (phocid weighting) or 218 dB Peak SPL			

Equations:

(1) $$= 39.1M^{1/3}\left(1+\frac{D_{Rm}}{10.081}\right)^{1/2} Pa-sec$$

(2) $$= 91.4M^{1/3}\left(1+\frac{D_{Rm}}{10.081}\right)^{1/2} Pa-sec$$

D_m = depth of the receiver (animal) in meters; M = mass of the animals in kg; SPL = sound pressure level

[1] Impulse calculated over a delivery time that is the lesser of the initial positive pressure duration or 20 percent of the natural period of the assumed-spherical lung adjusted for animal size and depth.
Notes: TTS = temporary threshold shift, PTS = permanent threshold shift, GI = gastrointestinal, M = mass of animals in kilograms, DRm = depth of receiver (animal) in meters, SEL = Sound Exposure Level, SPL = Sound Pressure Level (re 1 µPa), dB = decibels, dB re 1 µPa = decibels referenced to 1 micropascal, dB re 1 µPa^2-s = decibels referenced to 1 micropascal squared second

6.2.14.3.5 Onset of gastrointestinal tract injury

Evidence indicates that gas-containing internal organs, such as lungs and intestines, are the principal damage sites from shock waves in submerged terrestrial mammals (Clark and Ward 1943; Greaves et al. 1943; Richmond et al. 1973; Yelverton et al. 1973). Furthermore, slight injury to the gastrointestinal tract may be related to the magnitude of the peak shock wave pressure over the hydrostatic pressure and would be independent of the animal's size and mass (Goertner 1982).

There are instances where injury to the gastrointestinal tract could occur at a greater distance from the source than slight lung injury, especially for animals near the surface. Gastrointestinal tract injury from small test charges (described as "slight contusions") was observed at peak pressure levels as low as 104 pounds per square inch (psi), equivalent to a sound pressure level of 237 dB re 1 µPa (Richmond et al. 1973). This criterion was previously used by the Navy and NMFS for ship shock trials (Finneran and Jenkins (2012); 63 FR 230, 66 FR 87, 73 FR 143).

6.2.14.3.6 Slight lung injury and mortality

The most commonly reported internal bodily injury from impulse energy is hemorrhaging in the fine structure of the lungs. Biological damage is governed by the impulse of the underwater blast (pressure integrated over time), not peak pressure or energy (Richmond et al. 1973; Yelverton and Richmond 1981; Yelverton et al. 1973; Yelverton et al. 1975). Therefore, impulse was used as a metric upon which internal organ injury could be predicted. Species-specific minimal animal masses are used for determining impulse-based thresholds of slight lung injury and mortality. The Criteria and Thresholds for U.S. Navy Acoustic and Explosive Effects Analysis technical report (Finneran and Jenkins 2012) provides a nominal conservative body mass for each species based on newborn weights. In some cases body masses were extrapolated from similar species rather than the listed species. The scaling of lung volume to depth is conducted for all species since data is from experiments with terrestrial animals held near the water's surface.

Because the thresholds for onset of mortality and onset of slight lung injury are proportional to the cube root of body mass, the use of all newborn, or calf, weights rather than representative adult weights results in an over-estimate of effects to animals near an explosion. The range to onset mortality for a newborn compared to an adult animal of the same species can range from

less than twice to over four times as far from an explosion, depending on the differences in calf versus adult sizes for a given species and the size of the explosion. Considering that injurious high pressures due to explosions propagate away from detonations in a roughly spherical manner, the volumes of water in which the threshold for onset mortality may be exceeded are generally less than a fifth for an adult animal versus a calf.

The use of onset mortality and onset slight lung injury is a conservative method to estimate potential mortality and recoverable (non-mortal, non-PTS) injuries, respectively. When analyzing impulse-based effects, all animals within the range to these thresholds are assumed to experience the effect. The onset mortality and onset slight lung injury criteria is based on the impulse at which these effects are predicted for 1 percent of animals; the portion of animals affected would increase closer to the explosion. All animals receive the effect vice a percentage; therefore, these criteria conservatively over-estimate the number of animals that could be killed or injured.

Impulse thresholds for onset mortality and slight injury are indexed to 75 and 93 lb. (34 and 42 kg) for mammals, respectively (Richmond et al. 1973). The regression curves based on these experiments were plotted such that a prediction of mortality to larger animals could be determined as a function of positive impulse and mass (Craig Jr. 2001a). After correction for atmospheric and hydrostatic pressures and based on the cube root scaling of body mass, as used in the Goertner injury model (Goertner 1982), the minimum impulse for predicting onset of extensive (50 percent) lung injury for "1 percent Mortality" (defined as most survivors had moderate blast injuries and should survive on their own) and slight lung injury for "zero percent Mortality" (defined as no mortality, slight blast injuries) (Yelverton and Richmond 1981) were derived for each species. As the mortality threshold, the Navy chose to use the minimum impulse level predictive of 50 percent lung injury, even though this injury is likely to result in mortality to only 1 percent of exposed animals. Because the mortality criteria represents a threshold at which 99 percent of exposed animals would be expected to recover, this analysis overestimates the impact on individuals and populations from exposure to impulse sources.

6.2.14.4 *Behavioral Responses*

The behavioral response criteria are used to estimate the number of animals that may exhibit a behavioral response. In this analysis, animals may be behaviorally harassed in each modeled scenario (using the Navy Acoustic Effects Model) or within each 24-hour period, whichever is shorter. Therefore, the same animal could have a behavioral reaction multiple times over the course of a year.

6.2.14.4.1 Sonar and other active acoustic sources

Potential behavioral effects to marine mammals from non-impulse sound sources underwater were predicted using a behavioral response function. The received sound level is weighted with Type I auditory weighting functions (Southall et al. 2007b) before the behavioral response function is applied. The behavioral response functions estimate the percentage of an exposed population that is likely to exhibit behaviors that would qualify as harassment (as that term is defined by the MMPA applicable to military readiness activities, such as the Navy's testing and training with mid-frequency active sonar) at a given received level of sound. This effects analysis assumes that the potential consequences of exposure to non-impulsive sound on

individual animals would be a function of the received sound pressure level (SPL; dB re 1 µPa). For example, at 165 dB SPL (dB re 1µPa root mean square), the risk (or probability) of harassment is defined according to this function as 50 percent. This means that 50 percent of the individuals exposed at that received level would be predicted to exhibit a significant behavioral response. The behavioral response function applied to mysticetes (Figure 23) differs from that used for odontocetes (Figure 24) in having a shallower slope, which results in the inclusion of more behavioral events at lower amplitudes, consistent with observational data from North Atlantic right whales (Nowacek and Tyack 2007). Although the response functions differ, the intercepts on each figure highlight that each function has a 50 percent probability of harassment at a received level of 165 dB SPL. These analyses assume that sound poses a negligible risk to marine mammals if they are exposed to sound pressure levels below a certain basement value.

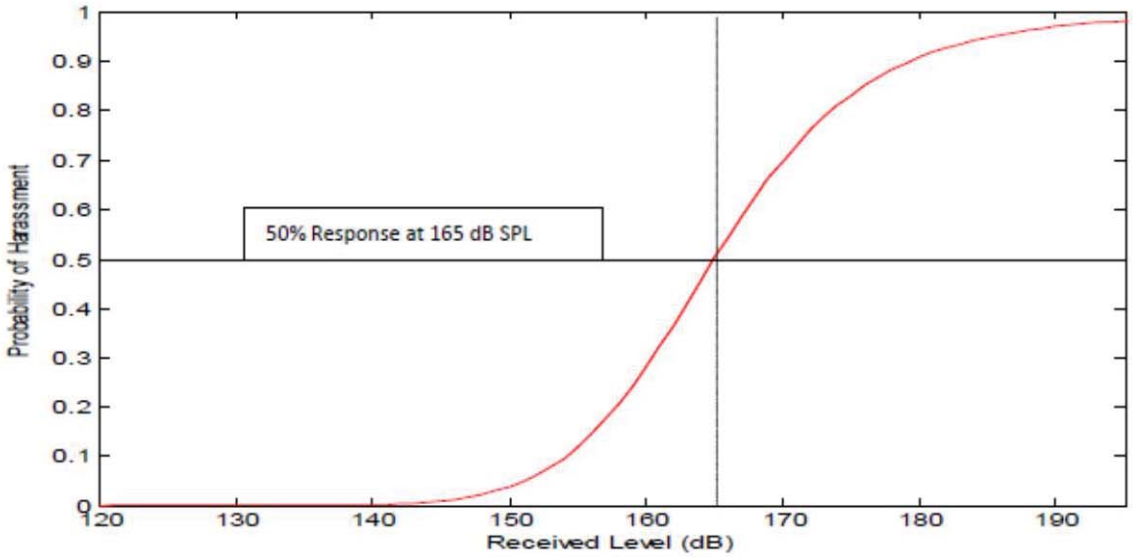

Figure 23. Behavioral response function applied to mysticetes.

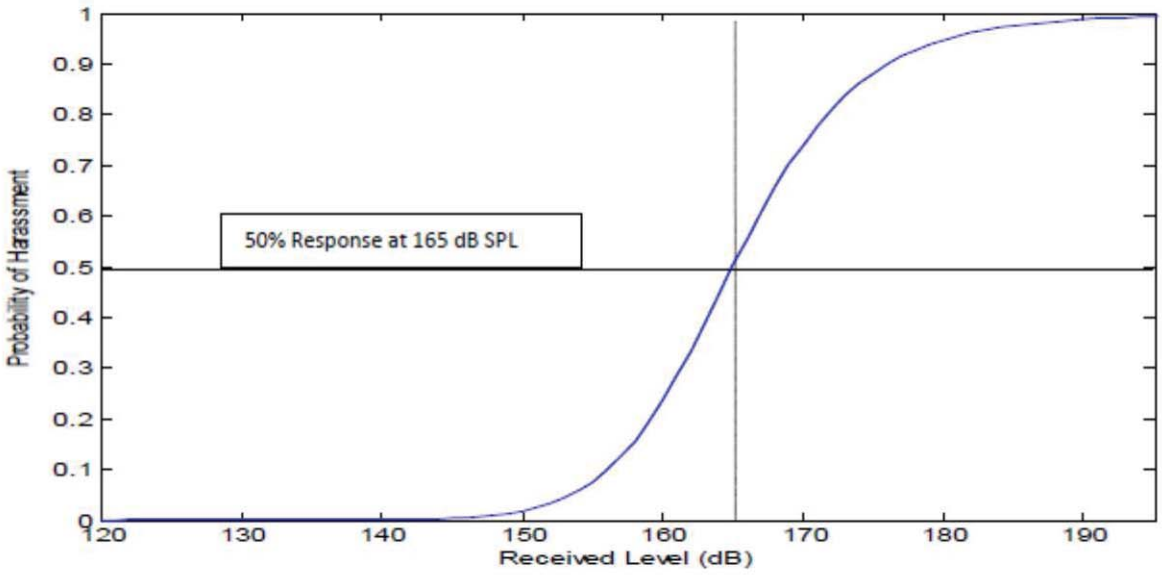

Figure 24. Behavioral response function applied to odontocetes and pinnipeds.

The distances over which the sound pressure level from four representative sonar sources is within the indicated 6-dB bins, and the percentage of animals that may exhibit a significant behavioral response under the mysticete and odontocete behavioral response function, are shown in Table 39 and Table 40 respectively.

Table 39. Range to Received Sound Pressure Level (SPL) in 6-dB Increments and Percentage of Behavioral Harassments for Low-Frequency Cetaceans under the Mysticete Behavioral Response Function for Four Representative Source Bins for the Action Area

6.2.14.4.2 Explosives

The thresholds for a behavioral response from explosives are listed in Table 41. Appropriate weighting values will be applied to the received impulse in one-third octave bands and the energy summed to produce a total weighted SEL value. For impulsive behavioral criteria, the

new weighting functions (Table 41) are applied to the received sound level before being compared to the threshold.

Table 41. Summary of behavioral response thresholds for marine mammals.

Group	Species	Behavioral thresholds for sonar and other active acoustic sources	Behavioral thresholds for explosions
Low-frequency cetaceans	All mysticetes	SPL: BRF (Type I Weighting)	167 dB re 1µPa2 -s SEL (Type II Weighting)
Mid-frequency cetaceans	Dolphins, beaked whales, and medium and large toothed whales	SPL: BRF (Type I Weighting)	167 dB re 1µPa2 -s SEL (Type II Weighting)
High-frequency cetaceans	Porpoises and *Kogia* spp.	SPL: BRF (Type I Weighting)	141 dB re 1µPa2 -s SEL (Type II Weighting)
Phocid seals (underwater)	Hawaiian monk seal	SPL: BRF (Type I Weighting)	172 dB re 1µPa2 -s SEL (Type I Weighting)
Otariid seals (underwater)	Guadalupe fur seal	SPL: BRF (Type I Weighting)	172 dB re 1µPa2 -s SEL (Type I Weighting)

BRF: Behavioral Response Function, SPL: Sound Pressure Level, SEL: Sound Exposure Level

If more than one explosive event occurs within any given 24-hour period within a training or testing activity, criteria are applied to predict the number of animals that may have a behavioral reactions. For events with multiple explosions, the behavioral threshold used in this analysis is 5 dB less than the TTS onset threshold (in SEL). Some multiple explosion events, such as certain gunnery exercises, may be treated as a single impulsive event because a few explosions occur closely spaced within a very short time (a few seconds). For single explosions at received sound levels below hearing loss thresholds, the most likely behavioral response is a brief alerting or orienting response. Since no further sounds follow the initial brief impulse, significant behavioral reactions would not be expected to occur.

Since impulse events can be quite short, it may be possible to accumulate multiple received impulses at sound pressure levels considerably above the energy-based criterion and still not be considered a behavioral take. All individual received impulses were treated as if they were 1 second long for the purposes of calculating cumulative SEL for multiple impulse events. For example, five air gun impulses, each 0.1 second long, received at 178 dB sound pressure level would equal a 175 dB SEL and would not be predicted as leading to a significant behavioral response. However, if the five 0.1 second pulses are treated as a 5-second exposure, it would yield an adjusted value of approximately 180 dB, exceeding the threshold. For impulses associated with explosions that have durations of a few microseconds, this assumption greatly overestimates effects based on SEL metrics such as TTS and PTS and behavioral responses.

6.3 Risk Assessment Framework - Sea Turtles

Direct injury to sea turtles from non-explosive sound sources, such as sonar, is unlikely because of relatively lower peak pressures and slower rise times than potentially injurious sources such as explosions. Nonexplosive sources also lack the strong shock waves that are associated with

explosions. Therefore, primary blast injury and barotrauma would not result from exposure to non-impulsive sources such as sonar, and are only considered for explosive detonations.

The potential for trauma in sea turtles exposed to explosive sources has been inferred from tests of submerged terrestrial mammals exposed to underwater explosions (Ketten et al. 1993; Richmond et al. 1973; Yelverton et al. 1973). The effects of an underwater explosion on a sea turtle depend upon several factors, including size, type, and depth of both the animal and the explosive, depth of the water column, and distance from the charge to the animal. Smaller sea turtles would generally be more susceptible to injury. The compression of blast-sensitive, gas-containing organs when a sea turtle increases depth reduces likelihood of injury to these organs. The location of the explosion in the water column and the underwater environment determines whether most energy is released into the water or the air and influences the propagation of the blast wave.

6.3.1 Primary Blast Injury and Barotrauma

The greatest potential for direct, non-auditory tissue impacts to sea turtles is primary blast injury and barotrauma after exposure to the shock waves of high-amplitude impulsive sources, such as explosions. Primary blast injuries result from the initial compression of a body exposed to the high pressure of a blast or shock wave. Primary blast injury is usually limited to gas-containing structures (e.g., lung and gut) and the pressure-sensitive components of the auditory system (discussed below) (Craig and Hearn 1998; SG 1991), although additional injuries could include concussive brain damage and cranial, skeletal, or shell fractures (Ketten 1995). Barotrauma refers to injuries caused when large pressure changes occur across tissue interfaces, normally at the boundaries of air-filled tissues such as the lungs. Primary blast injury to the respiratory system may be fatal depending on the severity of the trauma. Rupture of the lung may introduce air into the vascular system, producing air blockages that can restrict oxygen delivery to the brain and heart. Although often secondary in life-threatening severity to pulmonary blast trauma, the gastrointestinal tract can also suffer bruising and tearing from blast exposure, particularly in air-containing regions of the tract. Potential traumas include internal bleeding, bowel perforation, tissue tears, and ruptures of the hollow abdominal organs. Although hemorrhage of solid organs (e.g., liver, spleen, and kidney) from blast exposure is possible, rupture of these organs is rarely encountered. Non-lethal injuries could increase a sea turtle's risk of predation, disease, or infection.

6.3.2 Auditory Trauma

Components of the auditory system that detect smaller or more gradual pressure changes can also be damaged when overloaded at high pressures with rapid rise times. Rupture of the tympanic membrane, while not necessarily a serious or life-threatening injury, may lead to permanent hearing loss (Ketten 1993; Ketten 1995). No data exist to correlate the sensitivity of the tympanic membrane and middle and inner ear to trauma from shock waves from underwater explosions (Viada et al. 2008).

The specific impacts of bulk cavitation (the collapse of air spaces created by explosive detonations) on sea turtles are unknown. The presence of a sea turtle within the cavitation region created by the detonation of small charges could annoy, injure, or increase the severity of the injuries caused by the shock wave. The area of cavitation from a large charge, such as those used

in ship shock trials, is expected to result in mortality for smaller animals (Craig and Rye 2008). An animal located at (or near) the cavitation closure depth would be subjected to a short duration ("water hammer") pressure pulse; however, direct shock wave impacts alone would be expected to cause auditory system injuries and could cause internal organ injuries.

6.3.3 Hearing Loss

Hearing loss could effectively reduce the distance over which sea turtles can detect biologically relevant sounds. Both auditory trauma (a direct injury discussed above) and auditory fatigue may result in hearing loss, but the mechanisms responsible for auditory fatigue differ from auditory trauma. Hearing loss due to auditory fatigue is also known as threshold shift, a reduction in hearing sensitivity at certain frequencies. Threshold shift is the difference between hearing thresholds measured before and after an intense, fatiguing sound exposure. Threshold shift occurs when hair cells in the ear fatigue, causing them to become less sensitive over a small range of frequencies related to the sound source to which an animal was exposed. The actual amount of threshold shift depends on the amplitude, duration, frequency, and temporal pattern of the sound exposure. No studies are published on inducing threshold shift in sea turtles; therefore, the potential for the impact on sea turtles is inferred from studies of threshold shift in other animals.

Temporary threshold shift is a hearing loss that recovers to the original hearing threshold over a period. An animal may not even be aware of a TTS. It does not become deaf, but requires a louder sound stimulus (relative to the amount of TTS) to detect a sound within the affected frequencies. Temporary threshold shift may last several minutes to several days, depending on the intensity and duration of the sound exposure that induced the threshold shift (including multiple exposures).

Permanent threshold shift is a permanent hearing loss at a certain frequency range. Permanent threshold shift is non-recoverable due to the destruction of tissues within the auditory system. The animal does not become deaf, but requires a louder sound stimulus (relative to the amount of PTS) to detect a sound within the affected frequencies.

Little is known about how sea turtles use sound in their environment. Based on knowledge of their sensory biology (Bartol and Ketten 2006; Moein Bartol and Musick 2003), sea turtles may be able to detect objects within the water column (e.g., vessels, prey, predators) via some combination of auditory and visual cues. However, research examining the ability of sea turtles to avoid collisions with vessels shows they may rely more on their vision than auditory cues (Hazel et al. 2007). Similarly, while sea turtles may rely on acoustic cues to identify nesting beaches, they appear to rely on other non-acoustic cues for navigation, such as magnetic fields (Lohmann and Lohmann 1996a; Lohmann and Lohmann 1996b) and light (Avens and Lohmann 2003). Additionally, they are not known to produce sounds underwater for communication. As a result, we do not expect instances of TTS and PTS to have fitness consequences for individual turtles.

6.3.4 Auditory Masking

Auditory masking occurs when a sound prevents or limits the distance over which an animal detects other biologically relevant sounds. When a noise has a sound level above the sound of

interest, and in a similar frequency band, auditory masking could occur. Any sound above ambient noise levels and within an animal's hearing range could cause masking. The degree of masking increases with increasing noise levels; a noise that is just-detectable over ambient levels is unlikely to actually cause any substantial masking, whereas a louder noise may mask sounds over a wider frequency range. In addition, a continuous sound would have more potential for masking than a sound with a low duty cycle. In the open ocean, ambient noise levels are between about 60 and 80 dB re 1 µPa (NRC 2003), especially at lower frequencies (below 100 Hz) and inshore, ambient noise levels, especially around busy ports, can exceed 120 dB re 1 µPa.

Unlike hearing loss, which likely results in a stress response, behavioral changes resulting from auditory masking may not be coupled with a stress response. Another important distinction between masking and hearing loss is that masking only occurs in the presence of the sound stimulus, whereas hearing loss can persist after the stimulus is gone.

Little is known about how sea turtles use sound in their environment. Based on knowledge of their sensory biology (Bartol and Ketten 2006; Moein Bartol and Musick 2003), sea turtles may be able to detect objects within the water column (e.g., vessels, prey, predators) via some combination of auditory and visual cues. However, research examining the ability of sea turtles to avoid collisions with vessels shows they may rely more on their vision than auditory cues (Hazel et al. 2007). Similarly, while sea turtles may rely on acoustic cues to identify nesting beaches, they appear to rely on other non-acoustic cues for navigation, such as magnetic fields (Lohmann and Lohmann 1996a; Lohmann and Lohmann 1996b) and light (Avens and Lohmann 2003). Additionally, they are not known to produce sounds underwater for communication. As a result, sound may play a limited role in a sea turtle's environment. Therefore, the potential for masking may be limited.

6.3.5 Physiological Stress

Sea turtles may exhibit a behavioral response or combinations of behavioral responses upon exposure to anthropogenic sounds. If a sound is detected, a stress response (i.e., startle or annoyance) or a cueing response (based on a past stressful experience) can occur. Sea turtles naturally experience stressors within their environment and as part of their life histories. Changing weather and ocean conditions, exposure to diseases and naturally occurring toxins, lack of prey availability, social interactions with members of the same species, nesting, and interactions with predators all contribute to stress. Anthropogenic activities could provide additional stressors above and beyond those that occur in the absence of human activity.

Immature Kemp's ridley sea turtles show physiological responses to the acute stress of capture and handling through increased levels of the stress hormone corticosterone, along with biting and rapid flipper movement (Gregory and Schmid 2001). Though it should be noted that Kemp's ridley sea turtles are not found in the MITT Action Area, we would expect the turtles considered in this Opinion to have a similar physiological stress response. Captive olive ridley hatchlings showed heightened blood glucose levels indicating physiological stress (Zenteno et al. 2008). Repeated exposure to stressors, including human disturbance such as vessel disturbance and anthropogenic sound, may result in negative consequences to the health and viability of an individual or population (Gregory and Schmid 2001). Factors to consider when predicting a stress or cueing response is whether an animal is naïve or has prior experience with a stressor.

Prior experience with a stressor may be of particular importance as repeated experience with a stressor may dull the stress response via acclimation (Hazel et al. 2007).

6.3.6 Behavioral Reactions

Little is known about the hearing ability of sea turtles and their response to acoustic disturbance and thus analogous species for which data are available are used to estimate the potential behavioral reactions to sound. The response of a sea turtle to an anthropogenic sound will depend on the frequency, duration, temporal pattern, and amplitude of the sound, as well as the animal's prior experience with the sound and the context in which the sound is encountered (i.e., what the animal is doing at the time of the exposure). Distance from the sound source and whether it is perceived as approaching or moving away could also affect the way a sea turtle responds. Potential behavioral responses to anthropogenic sound could include startle reactions, disruption of feeding, disruption of migration, changes in respiration, alteration of swim speed, alteration of swim direction, and area avoidance.

It is also possible that behavioral reactions could lead to negative physiological consequences. For example, Garcia-Parraga et al. (2014) reported evidence of decompression sickness (DCS; e.g., gas embolism) in sea turtles following capture in trawls or gillnets, with a higher incidence of DCS when caught in deeper waters. It is possible that a sea turtle could have an extreme behavioral avoidance reaction (e.g., surfacing too quickly in an attempt to avoid noise) that could lead to DCS-like symptoms and fitness consequences. However, it should be noted that this is the first, and to our knowledge, only study that has documented DCS-like symptoms in sea turtles. Previous research has suggested sea turtles are protected against DCS through anatomical, physiological, and behavioral adaptations (Berkson 1967; Castellini 2012; Fossette et al. 2010b; Lutcavage and Lutz 1997; Piantadosi and Thalmann 2004). Given this uncertainty in the available literature and the lack of evidence that this sort of extreme behavioral avoidance reaction would be expected, we do not believe such a reaction is likely to occur and we do not consider DCS in sea turtles further in this Opinion.

6.3.6.1 *Behavioral Reactions to Impulsive Sound Sources*

Studies of sea turtle responses to sounds are limited, though a few studies examined sea turtle reactions to airguns, which produce broadband impulse sound. O'Hara and Wilcox (1990) attempted to create a sound barrier at the end of a canal using seismic airguns. They reported that loggerhead turtles kept in a 984 ft by 148 ft (300 m by 45 m) enclosure in a 10 m deep canal maintained a distance of 98 ft (30 m) from airguns fired every 15 seconds, with the strongest sound components within the 25 Hz to 1,000 Hz frequency range. McCauley et al. (2000) estimated that the received level at which turtles avoided sound in the O'Hara and Wilcox (1990) experiment was 175 to 176 dB re 1 µPa root mean square.

Moein Bartol et al. (1995) investigated the use of air guns to repel juvenile loggerhead sea turtles from hopper dredges. Sound frequencies of the airguns ranged from 100 Hz to 1,000 Hz at three levels: 175, 177, and 179 dB re 1 µPa at 1 m. The turtles avoided the airguns during the initial exposures (mean range of 24 m), but additional trials several days afterward did not elicit statistically significant avoidance. They concluded that this was due to either habituation or a temporary shift in the turtles' hearing capability.

McCauley et al. (2000) exposed caged green and loggerhead sea turtles to an approaching-departing single air gun to gauge behavioral responses. The trials showed that above a received level of 166 dB re 1 µPa root mean square, the turtles noticeably increased their swimming activity compared to non-operational periods, with swimming time increasing as air gun levels increased during approach. Above 175 dB re 1 µPa root mean square, behavior became more erratic, possibly indicating the turtles were in an agitated state (McCauley et al. 2000). The authors noted that the point at which the turtles showed erratic behavior and exhibited possible agitation would be expected to approximately equal the point at which active avoidance would occur for unrestrained turtles (McCauley et al. 2000).

No obvious avoidance reactions by free-ranging sea turtles, such as swimming away, were observed during a multi-month seismic survey using airgun arrays, although fewer sea turtles were observed when the seismic airguns were active than when they were inactive (Weir 2007). The author noted that sea state and the time of day affected both airgun operations and sea turtle surface basking behavior, making it difficult to draw conclusions from the data. Further, DeRuiter and Larbi Doukara (2012) noted diving behavior following airgun shots in loggerhead turtles, and noted a decreased dive probability with increasing distance from the airgun array.

6.3.6.2 *Behavioral Reactions to Non-Impulsive Sources*

No studies have been performed to examine the response of sea turtles to sonar. However, based on the limited range of hearing, they may respond to sources operating below 2 kHz but are unlikely to sense higher frequency sounds.

6.3.6.3 *Behavioral Reactions to Vessels*

Vessel noise and visual stimuli (vessels and shadows) could disturb sea turtles, and potentially elicit a startle response, avoidance, or other behavioral reaction. Sea turtles are frequently exposed to research, ecotourism, commercial, government, and private vessel traffic. Some sea turtles may habituate to vessel noise, and may be more likely to respond to the sight of a vessel rather than the sound of a vessel, although both may play a role in prompting reactions (Hazel et al. 2007).

6.3.6.4 *Behavioral Reactions to Aircraft and Missile Overflight*

Sea turtles may respond to both the physical presence (visual effects of the aircraft and shadows) and to the noise generated by aircraft. Helicopters may produce strong downdrafts, a vertical flow of air that becomes a surface wind, which can also affect an animal's behavior at or near the surface. In most cases, exposure of a sea turtle to fixed-wing or rotary-wing aircraft would last for only seconds as the aircraft quickly passes overhead. Animals would have to be at or near the surface at the time of an overflight to be exposed to appreciable sound levels or visual stimuli.

6.3.7 Repeated Exposures of Sea Turtles

Navy sonar systems are generally deployed from highly mobile vessels or in-water devices which do not directly target sea turtles. The typical duty cycle with most tactical anti-submarine warefare is about once per minute (Navy 2013). For example, a typical Navy vessel with hull mounted MFA sonar would travel over 0.3 kilometers between pings (based on a speed of 10 knots/hr and transmission rate of 1 ping/min). Based on this distance traveled and potential avoidance behavior of acoustically exposed animals, we expect repeat acoustic exposures

capable of eliciting a behavioral response to an individual over a brief period of time to be rare. For sonar devices that are stationary (e.g. dipped sonar), due to the duty cycle, duration of active transmission in a specific location, and mitigation measures (e.g. avoidance of visible sea turtles), we would not expect repeated exposures.

Establishing a causal link between anthropogenic noise and individual impacts as well as population viability is difficult to quantify and assess (McGregor 2013) (Read et al. 2014). Assessing the effects of sounds, both individually and cumulatively, on marine species is difficult because responses depend on a variety of factors incuding age class, prior experience, behavioral state at the time of exposure, and indirect effects. Responses may be also be influenced by other non-sound related factors (Ellison et al. 2011) (Kight and Swaddle 2011) (Goldbogen et al. 2013) (McGregor 2013) (Read et al. 2014) (Williams et al. 2014). Within the ocean environment, aggregate anthropogenic impacts have to be considered in context of natural variation and climate change (Boyd and Hutchins 2012). These contexts can include additive effects from two or more factors, multiplicity where response from two or more factors is greater than the sum of individual effects, synergism between factors and response, antagonism as a negative feedback between factors, acclimation as a short-term individual response, and adaptation as a long-term population change (Boyd and Hutchins 2012). To address aggregate impacts and responses from any changes due to processes such as habituation, tolerance, and sensitization, future experiments over an extended period of time still need further research (Bejder et al. 2009; Blickley et al. 2012) (Read et al. 2014).

Little is known about how sea turtles use sound in their environment. Based on knowledge of their sensory biology (Bartol and Ketten 2006; Moein Bartol and Musick 2003), sea turtles may be able to detect objects within the water column (e.g., vessels, prey, predators) via some combination of auditory and visual cues. However, research examining the ability of sea turtles to avoid collisions with vessels shows they may rely more on their vision than auditory cues (Hazel et al. 2007). Similarly, while sea turtles may rely on acoustic cues to identify nesting beaches, they appear to rely on other non-acoustic cues for navigation, such as magnetic fields (Lohmann and Lohmann 1996a; Lohmann and Lohmann 1996b) and light (Avens and Lohmann 2003). Additionally, they are not known to produce sounds underwater for communication. Therefore, repeated interruptions of a sea turtle's normal activity due to acoustic stressors is unlikely to lead to fitness consequences and long-term implications for the population. To result in significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no indication this is the case, particularly since foraging habitat would still be available in the environment following the cessation of acoustic exposure.

Sea turtles may habituate to, or become tolerant of, repeated exposures over time, such as ambient noise found in areas of high vessel traffic (Hazel et al. 2007). After initial avoidance reactions, loggerhead sea turtles habituated to repeated experimental exposures to airguns of up to a source level of 179 dB re 1 μPa in an enclosure. The habituation behavior was retained by the sea turtles when exposures were separated by several days (Moein Bartol et al. 1995). Individual sea turtles that are more tolerant may stay in a disturbed area, whereas individuals that

are more sensitive may leave for areas with less human disturbance. Animals that remain throughout the disturbance may be unable to leave the area for a variety of physiological or environmental reasons. However, given the highly migratory and wide ranging life histories of the species considered in this Opinion, we do not believe this will result from Navy training and testing activities in the MITT Action Area.

If sound exposure were to be concentrated in a relatively small geographic area over a long period of time (e.g., days or weeks during major training exercises), it would be possible for individuals confined to a specific area to be exposed to acoustic stressors (e.g., MFA sonar) multiple times during a relatively short time period. We do not expect this to occur as we would expect individuals to move and avoid areas where exposures to acoustic stressors are at higher levels (e.g., greater than 120 dB). Given sea turtles' mobility and large ranges, we would expect these individuals to temporaily select alternative foraging sites nearby until the exposure levels in their initially selected foraging area have decreased. Therefore, even temporary displacement from initially selected foraging habitat is not expected to impact the fitness of any individual animals because we would expect equivalent foraging to be available in close proximity. As a result of being capable of moving outside the range of behavioral responses from acoustic stressors, being physiologically less susceptible to acoustic stressors, and relying on senses other than hearing for important biological behaviors; we do not expect any fitness consequences from any individual animals nor do we expect any population level effects from behavioral responses.

6.3.8 Criteria for Predicting Acoustic and Explosive Impacts – Sea turtles

In this Opinion, we consider two primary categories of sound sources that the U.S. Navy used in its analyses of sound impacts on sea turtles: impulsive sources (e.g., explosives, airguns, weapons firing) and non-impulsive sources (e.g., sonar, pingers, and countermeasure devices). The Navy, in cooperation with NMFS, developed acoustic impacts criteria and thresholds for sea turtle exposures to various sound sources.

6.3.8.1 *Frequency weighting*

Animals generally do not hear equally well across their entire hearing range. Several studies using green, loggerhead, and Kemp's ridley turtles suggest sea turtles are most sensitive to low-frequency sounds, although this sensitivity varies slightly by species and age (Bartol et al. 1999a; Bartol and Ketten 2006; Lenhardt et al. 1994b; Ridgeway et al. 1969). Sea turtles possess an overall hearing range of approximately 100 Hz to 1 kHz, with an upper limit of 2 kHz (Bartol et al. 1999a; Bartol and Ketten 2006; Lenhardt et al. 1994b; Ridgeway et al. 1969). Because hearing thresholds are frequency-dependent, an auditory weighting function was developed for sea turtles (turtle-weighting, or T-weighting). The T-weighting function simply defines lower and upper frequency boundaries beyond which sea turtle hearing sensitivity decreases. The single frequency cutoffs at each end of the frequency range where hearing sensitivity begins to decrease are based on the most liberal interpretations of sea turtle hearing abilities (10 Hz and 2 kHz). These boundaries are precautionary and exceed the demonstrated or anatomy-based hypothetical upper and lower limits of sea turtle hearing. The T-weighting function adjusts the received sound level, based on sensitivity to different frequencies, emphasizing frequencies to which sea turtles are most sensitive and reducing emphasis on frequencies outside of their estimated useful range of hearing. For example, a 160 dB re 1 µPa tone at 10 kHz, far outside sea turtle best range of hearing, is estimated to be perceived by a sea turtle as a 130 dB re 1 µPa

sound (i.e., 30 dB lower). Stated another way, a sound outside of the range of best hearing would have to be more intense to have the same impact as a sound within the range of best hearing.

6.3.8.2 ***Hearing Loss – Temporary and Permanent Threshold Shift***

Whereas TTS represents a temporary reduction of hearing sensitivity, PTS represents tissue damage that does not recover and permanent reduced sensitivity to sounds over specific frequency ranges (see Section 6.3.8.2). To date, no known data are available on potential hearing impairments (i.e., TTS and PTS) in sea turtles. Sea turtles, based on their auditory anatomy (Lenhardt et al. 1985; Moein Bartol and Musick 2003; Wartzok and Ketten 1999; Wever 1978; Wyneken 2001), almost certainly have poorer absolute sensitivity (i.e., higher thresholds) across much of their hearing range than do the mid-frequency cetacean species. Therefore, applying TTS and PTS criteria derived from mid-frequency cetaceans to sea turtles provides a protective approach to estimating acoustic impacts to sea turtles (PTS and TTS data are not available for low-frequency cetaceans). Criteria for hearing loss due to onset of TTS and PTS are based on sound exposure level (for non-impulsive and impulsive sources) and peak pressure (for impulsive sources only).

To determine the sound exposure level, the turtle weighting function is applied to the acoustic exposure to emphasize only those frequencies within a sea turtle's hearing range. Multiple exposures within any 24-hour period are considered one continuous exposure for the purposes of calculating the received sound exposure level for a given individual. This conservatively assumes no recovery of hearing between exposures during a 24-hour period. The weighted sound exposure level is then compared to weighted threshold values for TTS and PTS. If the weighted exposure level meets or exceeds the weighted threshold, then the physiological impact (TTS or PTS) is assumed to occur. For impacts from exposures to impulsive sources, the metric (peak pressure or sound exposure level) and threshold level that results in the longest range to impact is used to predict impacts. Exposures are not calculated for sound sources with a nominal frequency outside the upper and lower frequency hearing limits for sea turtles.

In addition to being discussed below, thresholds for onset of TTS and PTS for impulsive and non-impulsive sounds are summarized in 6.3.8.2.2, 6.3.8.2.1, 6.3.8.2.4, and 6.3.8.2.3, respectively. As described in more detail below, it is critical to note that all turtle PTS and TTS thresholds were set too high. Therefore, quantitative impacts presented herein for PTS and TTS are conservative estimates.

Table 42. Sea Turtle Impact Threshold Criteria for Impulsive Sources

Impulsive Sound Exposure Impact	Threshold Value
Onset Mortality[1] (1% Mortality Based on Extensive Lung Injury)	$= 91.4M^{1/3}\left(1+\frac{D_{Rm}}{10.081}\right)^{1}/_{2}\ Pa-s$
Onset Slight Lung Injury[1]	$= 39.1M^{1/3}\left(1+\frac{D_{Rm}}{10.081}\right)^{1}/_{2}\ Pa-s$
Onset Slight Gastrointestinal Tract Injury	237 dB re 1 µPa SPL (104 psi)
Onset PTS	187 dB re 1 μPa^2 - s SEL (T^2) or 230 dB re 1 µPa Peak SPL
Onset TTS	172 dB re 1 μPa^2 - s SEL (T^2) or 224 dB re 1 µPa Peak SPL
Injury (Airguns)	190 dB re 1 µPa SPL root mean square[3]

dB: decibels, µPa: micropascals, PTS: permanent threshold shift, SEL: sound exposure level, SPL: sound pressure level, TTS: temporary threshold shift

[1] M=Mass of animals (kg) as shown for each species, DRm=depth of animal (m)

[2] (T): Turtle weighting function

[3] The time interval for determining the root mean square that which contains 90 percent of the total energy within the envelope of the pulse. This windowing procedure for impulse signals removes uncertainty about where to set the exact temporal beginning or end of the signal, which may be obscured by ambient noise.

Table 43. Sea Turtle Impact Threshold Criteria Used in Acoustic Modeling for Non-Impulse Sources

Physiological Thresholds	
Onset PTS	**Onset TTS**
198 dB SEL (T)	**178 dB SEL (T)**

dB: decibels; µPa: micropascals; PTS: permanent threshold shift; SEL: sound exposure level; SPL: sound pressure level; TTS: temporary threshold shift; (T): Turtle weighting function

Table 44 shows the average ranges to the potential effect from in-water explosions based on the thresholds for sea turtles. Some of the conservative assumptions made by the Navy for the impact modeling and criteria may cause the impact predictions to be overestimated, as follows:

- Many explosions from ordnance such as bombs and missiles actually explode upon impact with above-water targets. For this analysis, sources such as these were modeled as exploding at depths of 1 m, overestimating the amount of explosive and acoustic energy entering the water.

- For predicting TTS and PTS based on sound exposure level, the duration of an explosion is assumed to be 1 second. Actual detonation durations may be much shorter, so the actual sound exposure level at a particular distance may be lower.

- Mortality and slight lung injury criteria are based on juvenile turtle masses, which substantially increases that range to which these impacts are predicted to occur compared to the ranges that would be predicted using adult turtle masses.

- Animats are assumed to receive the full impulse of the initial positive pressure wave due to an explosion, although the impulse-based thresholds (onset mortality and onset slight lung injury)

Table 44. Range to impacts from In-Water Explosives on Sea Turtles from Representative Sources

Criteria Predicted Impact	Impact Predicted to Occur When Sea Turtle is at this Range (m) or Closer to a Detonation							
	Bin E-1 (0.0-0.5 lb. NEW)	Bin E-3 (0.6-2.6 lb. NEW)	Bin E-4 (2.6-6.0 lb. NEW)	Bin E-5 (6.0-10.0 lb. NEW)	Bin E-8 (21.0-60.0 lb. NEW)	Bin E-10 (251-500 lb. NEW)	Bin E-11 (501-1,000 lb. NEW)	Bin E-12 (1000-1,651 lb. NEW)
Onset Mortality (1% Mortality)	4	26	51	46	102	164	458	199
Onset Slight Lung Injury	17	50	130	85	179	284	816	343
Onset Slight GI Tract Injury	40	60	175	55	106	184	201	250
Permanent Threshold Shift[1]	67	196	215	162	424	873	809	1,251
Temporary Threshold Shift[1]	90	724	421	288	844	1,975	1,693	2,640
Behavioral Response	144	1,512	796	565	1,458	3,217	3,015	3,962

6.3.8.2.1 Temporary Threshold Shift – Non-impulsive sources

Based on best available science regarding TTS in marine vertebrates (Finneran et al. 2002; Southall et al. 2007c) and the lack of information regarding TTS in sea turtles, the total T-weighted sound exposure level of 178 dB re 1 micro Pascal squared second (µPa2 -s) is used to estimate exposures resulting in TTS for sea turtles. The T-weighting function is used in conjunction with this non-impulsive criterion, which effectively provides an upper cutoff of 2 kHz. The T-weighted non-impulsive TTS threshold of 178 dB re 1 µPa2 -s sound exposure

level was inadvertently based on Type II weighted cetacean TTS data rather than Type I weighted cetacean TTS data. This resulted in incorrectly lowering the turtle TTS threshold by 17 dB. The sea turtle non-impulsive TTS threshold, based on mid-frequency cetacean data, should be 17 dB higher than 178 dB re 1 µPa2 -s. Because an incorrectly lowered threshold was used to quantitatively analyze acoustic impacts on sea turtles, the quantitative impacts presented herein for non-impulsive TTS are conservative (i.e., over-predicted).

6.3.8.2.2 Temporary Threshold Shift – Impulsive sources

Based on best available science regarding TTS in marine vertebrates (Finneran et al. 2005b; Finneran et al. 2000; Finneran et al. 2002; Nachtigall et al. 2003; Nachtigall et al. 2004; Schlundt et al. 2000) and the lack of information regarding TTS in sea turtles, the respective total T-weighted sound exposure level of 172 dB re 1 μPa^2-s or peak pressure of 224 dB re 1 µPa (23 pounds per square inch [psi]) is used to estimate exposures resulting in TTS for sea turtles. The T-weighting function is applied when using the sound exposure level-based thresholds to predict TTS.

The T-weighted impulsive TTS threshold of 172 dB re 1 μPa^2-s sound exposure level was inadvertently based on Type II weighted cetacean TTS data rather than Type I weighted cetacean TTS data. This resulted in incorrectly lowering the turtle TTS threshold. The sea turtle impulsive TTS threshold, based on Type I mid-frequency cetacean data, should be 183 dB re 1 μPa^2-s. Because an incorrectly lowered threshold was used to quantitatively analyze acoustic impacts to sea turtles, the quantitative impacts presented herein for impulsive TTS are conservative (i.e., over-predicted).

6.3.8.2.3 Permanent Threshold Shift – Non-impulsive sources

Since no studies were designed to intentionally induce PTS in sea turtles, levels for onset of PTS for these animals must be estimated using TTS data and relationships between TTS and PTS established in terrestrial mammals. Permanent threshold shift can be estimated based on the growth rate of a threshold shift and the level of threshold shift required to potentially become non-recoverable. A variety of terrestrial and marine mammal data show that threshold shifts up to 40 to 50 dB may be recoverable, and that 40 dB is a reasonable upper limit of a threshold shift that does not induce PTS (Southall et al. 2007b) (Ward et al. 1958; Ward et al. 1959). This analysis assumes that continuous-type exposures producing threshold shifts of 40 dB or more always result in some amount of PTS. Data from terrestrial mammal testing (Ward et al. 1958, 1959) show TTS growth of 1.5 to 1.6 dB for every 1 dB increase in sound exposure level. The difference between minimum measureable TTS onset (6 dB) and the 40 dB upper safe limit of TTS yields a difference of 34 dB. When divided by a TTS growth rate of 1.6 dB TTS per dB sound exposure level, there is an indication that an increase in exposure of a 21.25 dB sound exposure level would result in 40 dB of TTS. For simplicity and conservatism, the number was rounded down to 20 dB sound exposure level. Therefore, non-impulsive exposures of 20 dB sound exposure level above those producing a TTS may be assumed to produce a PTS. The onset of TTS threshold of 195 dB re 1 μPa^2-s for sea turtles has a corresponding onset of PTS threshold of 198 dB re 1 μPa^2-s. The T-weighting function is applied when using the sound exposure level-based thresholds to predict PTS.

The T-weighted non-impulsive TTS threshold of 178 dB re 1 μPa^2-s sound exposure level was inadvertently based on Type II weighted cetacean TTS data rather than Type I weighted cetacean TTS data. This resulted in incorrectly lowering the turtle TTS threshold by 17 dB; consequently, also incorrectly lowering the sea turtle PTS threshold by 17 dB. The sea turtle non-impulsive PTS threshold, based on mid-frequency cetacean data, should be 17 dB higher than 198 dB re 1 μPa^2-s. Because an incorrectly lowered threshold was used to quantitatively analyze acoustic impacts to sea turtles, the quantitative impacts presented herein for non-impulsive PTS are conservative (i.e., overpredicted).

6.3.8.2.4 Permanent Threshold Shift – Impulsive sources

Because marine mammal and sea turtle PTS data from impulsive exposures do not exist, onset of PTS levels for these animals are estimated by adding 15 dB to the sound exposure level-based TTS threshold and adding 6 dB to the peak pressure-based thresholds. These relationships were derived by Southall et al. (Southall et al. 2007b) from impulsive noise TTS growth rates in chinchillas. This results in onset of PTS thresholds of total weighted sound exposure level of 187 dB re 1 μPa^2-s or peak pressure of 230 dB re 1 µPa for sea turtles. The T-weighting function is applied when using the sound exposure level-based thresholds to predict PTS.

The T-weighted impulsive PTS threshold of 187 dB re 1 μPa^2-s sound exposure level was inadvertently based on Type II weighted cetacean TTS data rather than Type I weighted cetacean TTS data. This resulted in incorrectly lowering the turtle TTS threshold. The sea turtle impulsive PTS threshold, based on Type I mid-frequency cetacean data, should be 198 dB re 1 μPa^2-s. Because an incorrectly lowered threshold was used to quantitatively analyze acoustic impacts to sea turtles, the quantitative impacts presented herein for impulsive PTS are conservative (i.e., over-predicted).

6.3.8.3 *Mortality and Injury from Explosions*

There is a considerable body of laboratory data on actual injuries from impulsive sounds, usually from explosive pulses, obtained from tests with a variety of vertebrate species (e.g., (Goertner et al. 1994; Richmond et al. 1973; Yelverton et al. 1973)). Based on these studies, potential impacts, with decreasing likelihood of serious injury or lethality, include onset of mortality, onset of slight lung injury, and onset of slight gastrointestinal injury. In the absence of data specific to sea turtles, criteria developed to assess impacts to protected marine mammals are also used to assess impacts to protected sea turtles. These criteria are discussed below.

6.3.8.3.1 Criteria for Mortality and Slight Lung Injury

In air or submerged, the most commonly reported internal bodily injury to sea turtles from explosive detonations is hemorrhaging in the fine structure of the lungs. The likelihood of internal bodily injury is related to the received impulse of the underwater blast (pressure integrated over time), not peak pressure or energy (Richmond et al. 1973; Yelverton and Richmond 1981; Yelverton et al. 1973; Yelverton et al. 1975). Therefore, impulse is used as a metric upon which internal organ injury can be predicted. Onset mortality and onset slight lung injury are defined as the impulse level that would result in one percent mortality (most survivors have moderate blast injuries and should survive) and zero percent mortality (recoverable, slight blast injuries) in the exposed population, respectively. Criteria for onset mortality and onset

slight lung injury were developed using data from explosive impacts on mammals (Yelverton and Richmond 1981).

The impulse required to cause lung damage is related to the volume of the lungs. The lung volume is related to both the size (mass) of the animal and compression of gas-filled spaces at increasing water depth. Turtles have relatively low lung volume to body mass and a relatively stronger anatomical structure compared to mammals; therefore application of the criteria derived from studies of impacts of explosions on mammals may be conservative. Table 45 provides a conservative body mass for each sea turtle species based on juvenile mass.

Juvenile body mass was selected for analysis given the early rapid growth of these reptiles (newborn turtles weigh less than 0.5 percent of maximum adult body mass). In addition, small turtles tend to remain at shallow depths in the surface pressure release zone, reducing potential exposure to injurious impulses. Therefore, use of hatchling weight would provide unrealistically low thresholds for estimating injury to sea turtles. The use of juvenile body mass rather than adult body mass was chosen to produce reasonably conservative estimates of injury.

Table 45. Species-Specific Sea Turtle Masses for Determining Onset of Extensive and Slight Lung Injury Thresholds

Common Name	Juvenile Mass (kg)	Reference
Loggerhead sea turtle	8.4	Southwood et al. (2007)
Green sea turtle	8.7	Wood and Wood (1993)
Hawksbill sea turtle	7.4	Okuyama et al. (2010)
Olive ridley sea turtle	6.3	McVey and Wibbels (1984) and Caillouet et al. (1986)
Leatherback sea turtle	34.8	Jones (2009)

The scaling of lung volume to depth is conducted because data come from experiments with terrestrial animals held near the water's surface. The calculation of impulse thresholds consider depth of the animal to account for compression of gas-filled spaces that are most sensitive to impulse injury. The impulse required for a specific level of injury (impulse tolerance) is assumed to increase proportionally to the square root of the ratio of the combined atmospheric and hydrostatic pressures at a specific depth with the atmospheric pressure at the (Goertner 1982).

Very little information exists about the impacts of underwater detonations on sea turtles. Impacts of explosive removal operations on sea turtles range from non-injurious impacts (e.g., acoustic annoyance, mild tactile detection, or physical discomfort) to varying levels of injury (i.e., non-lethal and lethal injuries) (Klima et al. 1988; Viada et al. 2008). Often, impacts of explosive events on turtles must be inferred from documented impacts on other vertebrates with lungs or other-gas containing organs, such as mammals and most fishes (Viada et al. 2008). The methods used by Goertner (1982) to develop lung injury criteria for marine mammals may not be directly applicable to sea turtles, as it is not known what degree of protection to internal organs from the shock waves is provided to sea turtles by their shell (Viada et al. 2008). However, the general principles of the Goertner model are applicable, and should provide a protective approach to assessing potential impacts on sea turtles. The Goertner method predicts a minimum primary positive impulse value for onset of slight lung injury and onset of mortality, adjusted for assumed

lung volume (correlated to animal mass) and depth of the animal. These equations are shown in Table 42.

6.3.8.3.2 Criteria for Onset of Gastrointestinal Tract Injury

Without data specific to sea turtles, data from tests with terrestrial animals are used to predict onset of gastrointestinal tract injury. Gas-containing internal organs, such as lungs and intestines, were the principle damage sites from shock waves in submerged terrestrial mammals (Richmond et al. 1973; Yelverton et al. 1973). Furthermore, slight injury to the gastrointestinal tract may be related to the magnitude of the peak shock wave pressure over the hydrostatic pressure, and would be independent of the animal's size and mass (Goertner 1982). Slight contusions to the gastrointestinal tract were reported during small charge tests (Richmond et al. 1973), when the peak was 237 dB re 1 µPa. Therefore, this value is used to predict onset of gastrointestinal tract injury in sea turtles exposed to explosions.

6.3.8.4 *Criteria for Behavioral Reactions*

A sea turtle's behavioral responses to sound are assumed to be variable and context specific. For instance, a single impulse may cause a brief startle reaction. A sea turtle may swim farther away from the sound source, increase swimming speed, change surfacing time, and decrease foraging if the stressor continues to occur. For each potential behavioral change, the magnitude of the change ultimately would determine the severity of the response; most responses would be short-term avoidance reactions.

A few studies reviewed in Section 6.3.6, investigated behavioral responses of sea turtles to impulsive sounds emitted by airguns (McCauley et al. 2000; Moein Bartol et al. 1995; O'Hara and Wilcox 1990). There are no studies of sea turtle behavioral responses to sonar. Cumulatively, available airgun studies indicate that perception and a behavioral reaction to a repeated sound may occur with sound pressure levels greater than 166 dB re 1 µPa root mean square, and that more erratic behavior and avoidance may occur at higher thresholds around 175 to 179 dB re 1 µPa root mean square (McCauley et al. 2000; Moein Bartol et al. 1995; O'Hara and Wilcox 1990). When exposed to impulsive acoustic energy from an airgun above 175 dB re 1 µPa root mean square, sea turtle behavior becomes more erratic, possibly indicating the turtles were in an agitated state (McCauley et al. 2000). A received level of 175 dB re 1 µPa root mean square is more likely to be the point at which avoidance may occur in unrestrained turtles, with a comparable sound exposure level of 160 dB re 1 µPa2 -s (McCauley et al. 2000). Airgun studies used sources that fired repeatedly over some duration. For single impulses at received levels below threshold shift (hearing loss) levels, the most likely behavioral response is assumed to be a startle response. Since no further sounds follow the initial brief impulse, the biological significance is considered to be minimal.

Behavioral responses of sea turtles to airgun exposures in caged enclosures are likely to be different than those from turtles exposed to impulsive acoustic sources from MITT activities in the open environment. Although information regarding the behavioral response of sea turtles to acoustic stressors is generally lacking, McCauley et al. (2000) provides an indication that 175 dB re 1 µPa root mean square is a reasonable threshold criterion in the absence of more rigorous experimental or observational data. The 175 dB re 1 µPa root mean square threshold criterion for behavioral take in sea turtles may change with better available information in the future, but

currently is the best available science. To assess the number of sea turtles expected to behaviorally respond to acoustic stress all turtles exposed to sound equal to, or greater than, 175 dB and less than the criterion for TTS were summed. No attempt to process these exposures or evaluate the effectiveness of mitigation measures was made, suggesting any behavioral take estimates of sea turtles from acoustic stressors are likely overestimates. We are unaware of any sea turtle response studies to non-impulsive acoustic energy; therefore, we used the same criteria as those for impulsive acoustic stressors.

6.4 Risk Assessment Framework – Scalloped Hammerhead Shark

This section is largely based on a technical report prepared for the Navy: Effects of Mid- and High-Frequency Sonars on Fish (Popper 2008b). Additionally, Popper and Hastings (Popper and Hastings 2009a; Popper and Hastings 2009b) provide a critical overview of some of the most recent research regarding potential effects of anthropogenic sound on fish.

Studies of the effects of human-generated sound on fish have been reviewed in numerous places (e.g., (Hastings and Popper 2005; NRC 1994; Popper 2003; Popper 2008a; Popper and Hastings 2009a; Popper and Hastings 2009b; Popper et al. 2004)). Most investigations, however, have been in the gray literature (non-peer-reviewed reports—see (Hastings and Popper 2005; Popper 2008a; Popper and Hastings 2009a) for extensive critical reviews of this material). Studies have been published assessing the effect on fish of short-duration, high-intensity signals such as might be found near high-intensity sonar, pile driving, or seismic air guns. The investigators in such studies examined short-term effects that could result in death to the exposed fish, as well as hearing loss and long-term consequences (Doksaeter et al. 2009; Govoni et al. 2003; McCauley et al. 2003; Popper et al. 2007; Popper et al. 2005). Information is also discussed from a technical report that resulted from a working group established by the Acoustical Society of America on sound exposure guidelines for fishes and sea turtles (Popper et al. 2014).

6.4.1 Direct Injury of Scalloped Hammerhead Sharks from Non-Impulsive Acoustic Stressors

Potential direct injuries from non-impulsive sound sources, such as sonar, are unlikely because of the relatively lower peak pressures and slower rise times than potentially injurious sources such as explosives. Non-impulsive sources also lack the strong shock wave such as that associated with an explosion. The theories of sonar induced acoustic resonance, bubble formation, neurotrauma, and lateral line system injury are discussed below, although these would likely occur only in fish very close to the sound source and are therefore unlikely to impact entire populations of fish or have an impact in a large area.

No studies have indicated any physiological damage to adult fish from mid-frequency active sonar. Kvadsheim and Sevaldsen (2005) showed that intense sonar activities in herring spawning areas affected less than 0.3 percent of the total juvenile stock. Jørgensen et al. (2005) exposed fish larvae and juveniles representing four species (of three families) to sounds that were designed to simulate mid-frequency sonar transmissions (1 to 6.5 kHz) to study the effects of the exposure on the survival, development, and behavior of the larvae and juveniles (the study used larvae and juveniles of Atlantic herring (*Clupea harengus*) Atlantic cod (*Gadus morhua*), saithe (*Pollachius virens),* and spotted wolffish (*Anarhichas minor*)). The researchers placed the fish in plastic bags three meters from the sound source and exposed them to between four and 100

pulses of one-second duration of pure tones at 1.5, 4, and 6.5 kHz. The fish in only two groups out of the 42 tested exhibited adverse effects beyond a behavioral response. These two groups were both composed of herring, a hearing specialist, and were tested with sound pressure levels of 189 dB re 1 µPa, which resulted in a post-exposure mortality of 20 to 30 percent. In the remaining 40 tests, there were no observed effects on behavior, growth (length and weight), or the survival of fish that were kept as long as 34 days post exposure. While statistically significant losses were documented in the two groups impacted, the researchers only tested that particular sound level once, so it is not known if this increased mortality was due to the level of the test signal or to other unknown factors.

Halvorsen et al. (2012) exposed rainbow trout to simulated MFA (2.8 to 3.8 kHz) sonar at received sound pressure levels of 210 dB re 1 uPa, resulting in cumulative sound exposure levels of 220 dB re 1 uPa. The authors did not observe any mortality or hearing sensitivity changes in rainbow trout and suggested that the frequency range of MFA sonar may be above the most sensitive hearing range of the species. Similarly, Kane et al. (2010) found that low-and mid-frequency exposure caused no acute, gross or histopathology, nor any mortality to rainbow trout, *I. punctatus*, or *Lepomis* sp. Popper et al. (2008c; 2007; Popper and Hastings 2009b) investigated the effects of exposing several fish species to the U.S. Navy's SURTASS LFA sonar, focusing on the hearing and on non-auditory tissues. Their study exposed the fish to LFA sonar pulses for time intervals that would be substantially longer than what would occur in nature, but the fish did not experience mortalities or damage to body tissues at the gross or histological level.

Swim bladder resonance is a function of the size and geometry of the air cavity, depth of the fish, and frequency of the transmitted signal. Wavelengths associated with mid-frequency sounds are shorter than wavelengths associated with lower frequency sounds. It is the lower frequencies that are expected to produce swim bladder resonance in adult fishes. Resonance frequencies for juvenile fish are 1 to 8 kHz and can escalate physiological impact (Kvadsheim and Sevaldsen 2005; Lovik and Hovem 1979). Scalloped hammerhead sharks do not have a swim bladder; therefore, they are likely less susceptible to acoustic stressors than many marine fish.

High sound pressure levels may cause bubbles to form from micronuclei in the blood stream or other tissues of animals, possibly causing embolism damage (Ketten 1998). Fish have small capillaries where these bubbles could be caught and lead to the rupturing of the capillaries and internal bleeding. It has also been speculated that this phenomena could also take place in the eyes of fish due to potentially high gas saturation within the fish's eye tissues (Popper and Hastings 2009b) (Popper and Hastings 2009a). As reviewed in Popper and Hastings (Popper and Hastings 2009a), Hastings (Hastings 1990; Hastings 1995) found 'acoustic stunning' (loss of consciousness) in blue gouramis (*Trichogaster trichopterus*) following an 8-minute exposure to a 150 Hz pure tone with a peak sound pressure level (SPL) of 198 dB re 1 µPa. This species of fish has an air bubble in the mouth cavity directly adjacent to the animal's braincase that may have caused this injury. Hastings (Hastings 1990; Hastings 1995) also found that goldfish exposed to two hours of continuous wave sound at 250 Hz with peak pressures of 204 dB re 1 µPa, and fathead minnows exposed to 0.5 hours of 150 Hz continuous wave sound at a peak level of 198 dB re 1 µPa did not survive. The only study on the effect of exposure of the lateral line system to continuous wave sound (conducted on one freshwater species) suggests no effect on these sensory cells by intense pure tone signals (Hastings et al. 1996).

Popper et al. (2014) developed sound exposure guidelines for fishes exposed to low and mid-frequency naval sonar. The authors did not did not provide evidence that injury or mortality could occur from naval sonar, and indicated that if injury or mortality occurs, it is thought to begin at higher sound levels than have been tested to date. The authors concluded that the relative risk of injury or mortality to fish with no swim bladders (e.g., scalloped hammerhead shark) exposed to low and mid-frequency sonar was low, no matter the distance from the source.

6.4.2 Primary Blast Injury and Barotrauma

The greatest potential for direct, non-auditory tissue effects in fish is primary blast injury and barotrauma following exposure to explosions. Primary blast injury refers to those injuries that result from the initial compression of a body exposed to a blast wave. Primary blast injury is usually limited to gas-containing structures (e.g., swim bladder) and the auditory system. Barotrauma refers to injuries caused when the swim bladder or other gas-filled structures vibrate in response to the signal, particularly if there is a relatively sharp rise-time and the walls of the structure strike near-by tissues and damage them. The relative risk of injury or mortality to scalloped hammerhead sharks with no swim bladders exposed to explosions is anticipated to be much lower than fish with swim bladders.

An underwater explosion generates a shock wave that produces a sudden, intense change in local pressure as it passes through the water (DoN 1998; DoN 2001). Pressure waves extend to a greater distance than other forms of energy produced by the explosion (i.e., heat and light) and are therefore the most likely source of negative effects to marine life from underwater explosions (Craig Jr. 2001b; DoN 2006; SIO 2005). The shock wave from an underwater explosion is lethal to fish at close range causing massive organ and tissue damage and internal bleeding (Keevin and Hempen 1997). At greater distance from the detonation point, the extent of mortality or injury depends on a number of factors including fish size, body shape, orientation, and species (Keevin and Hempen 1997; Wright 1982). Additional factors include the current physical condition of the fish and the presence of a swim bladder. Again, scalloped hammerhead sharks do not have swim bladders. At the same distance from the source, larger fish are generally less susceptible to death or injury, elongated forms that are round in cross-section are less at risk than deep-bodied forms, and fish oriented sideways to the blast suffer the greatest impact (Edds-Walton and Finneran 2006; O'Keefe and Young 1984; Wiley et al. 1981; Yelverton et al. 1975). Species with gas-filled organs have higher mortality than those without them (Continental Shelf Associates Inc. 2004; Goertner et al. 1994).

Two aspects of the shock wave appear most responsible for injury and death to fish: the received peak pressure and the time required for the pressure to rise and decay (Dzwilewski and Fenton 2002). Higher peak pressure and abrupt rise and decay times are more likely to cause acute pathological effects (Wright and Hopky 1998). Rapidly oscillating pressure waves might rupture the kidney, liver, spleen, and sinus and cause venous hemorrhaging (Keevin and Hempen 1997). They can also generate bubbles in blood and other tissues, possibly causing embolism damage (Ketten 1998). Oscillating pressure waves might also burst gas-containing organs. The swim bladder, the gas-filled organ used by most bony fish to control buoyancy, is the primary site of damage from explosives (Wright 1982; Yelverton et al. 1975). Gas-filled swim bladders resonate at different frequencies than surrounding tissue and can be torn by rapid oscillation between high- and low-pressure waves. The range over which damage may occur in a fish without a swim

bladder, such as the scalloped hammerhead shark, is on the order of 100 times less than that for swim bladder fish (Popper et al. 2014).

Studies that have documented fish killed during planned underwater explosions indicate that most fish that die do so within one to four hours, and almost all die within a day (Hubbs and Rechnitzer 1952; Yelverton et al. 1975). Fitch and Young (1948) found that the type of fish killed changed when blasting was repeated at the same marine location within 24 hours of previous blasting. They observed that most fish killed on the second day were scavengers, presumably attracted by the victims of the previous day's blasts. However, fishes collected during these types of studies have mostly been recovered floating on the water's surface. Gitschlag et al. (2001) collected both floating fish and those that were sinking or lying on the bottom after explosive removal of nine oil platforms in the northern Gulf of Mexico. They found that 3 to 87 percent (46 percent average) of the specimens killed during a blast might float to the surface. Other impediments to accurately characterizing the magnitude of fish mortality included currents and winds that transported floating fishes out of the sampling area and predation by seabirds or other fishes. Popper et al. (2014) developed sound exposure guidelines for fishes and generally estimated that mortality and mortal injury would occur when the peak sound pressure level from a single explosion exceeds 229 to 234 dB re 1 μPa.

There have been few studies of the impact of underwater explosions on early life stages of fishes (eggs, larvae, juveniles). Fitch and Young (1948) reported the demise of larval anchovies exposed to underwater blasts off California, and Nix and Chapman (1985) found that anchovy and eulachon larvae died following the detonation of buried charges. It has been suggested that impulsive sounds, such as that produced by seismic airguns, may cause damage to the cells of the lateral line in fish larvae and fry when in close proximity (15 ft. [5 m]) to the sound source (Booman et al. 1996). Similar to adult fishes, the presence of a swim bladder contributes to shock wave-induced internal damage in larval and juvenile fishes (Settle et al. 2002). Shock wave trauma to internal organs of larval pinfish and spot from shock waves was documented by Govoni et al. (2003). These were laboratory studies, however, and have not been verified in the field.

Interim criteria for injury of fish were discussed in Stadler and Woodbury (2009). The onset of physical injury would be expected if either the peak sound pressure level exceeds 206 dB re 1 μPa, or the cumulative sound exposure level, accumulated over all pile strikes generally occurring within a single day, exceeds 187 dB re 1 micropascal squared second (μPa^2-s) for fish two grams or larger, or 183 dB re 1 μPa^2-s for smaller fish (Stadler and Woodbury 2009). A more recent study by Halvorsen et al. (2011) used carefully controlled laboratory conditions to determine the level of pile driving sound that may cause a direct injury to the fish tissues (barotrauma). The investigators found that juvenile Chinook salmon (*Oncorhynchus tshawytscha*) received less than a single strike sound exposure level of 179 to 181 dB re 1μ Pa^2-s and cumulative sound exposure level of less than 211 dB re 1 μPa^2-s over the duration of the pile driving activity would sustain no more than mild, non-life-threatening injuries.

6.4.3 Hearing Loss

Exposure to high intensity sound can cause hearing loss, also known as a noise-induced threshold shift, or simply a threshold shift (Miller 1974). A TTS is a temporary, recoverable loss

of hearing sensitivity. A TTS may last several minutes to several weeks and the duration may be related to the intensity of the sound source and the duration of the sound (including multiple exposures). A permanent threshold shift (PTS) is non-recoverable, results from the destruction of tissues within the auditory system, and can occur over a small range of frequencies related to the sound exposure. As with temporary threshold shift, the animal does not become deaf but requires a louder sound stimulus (relative to the amount of PTS) to detect a sound within the affected frequencies; however, in this case, the effect is permanent.

Permanent hearing loss, or permanent threshold shift has not been documented in fish. The sensory hair cells of the inner ear in fish can regenerate after they are damaged, unlike in mammals where sensory hair cells loss is permanent (Lombarte et al. 1993; Smith et al. 2006a). As a consequence, any hearing loss in fish may be as temporary as the timeframe required to repair or replace the sensory cells.

As we discussed in the *Status of Listed Resources*, Scalloped hammerhead sharks have an inner ear capable of detecting high-frequency sounds and a lateral line capable of detecting water motion caused by low frequencies (Hastings and Popper 2005; Popper and Schilt 2009). Data for cartilaginous fish suggest detection of sounds from 20 Hz to 1000 Hz with the highest sensitivity to sounds at the lower ranges (Casper et al. 2003; Casper and Mann 2006; Myrberg Jr. 2001). Sharks generally react to low-frequency tones in this range and are particularly responsive to sounds lower than 375 Hz, which makes them able to perceive sounds including underwater movement and thrashing over long distances.

The “otoliths” or fish ear bones in teleosts (ray-finned, bony fishes) are generally composed of a solid calcium carbonate matrix, while elasmobranch ear structures are calcium carbonate, with exogenous siliceous material, in a gelatinous matrix. It has been suggested that ears with otoliths of a higher density are more sensitive to accelerations (Lychakov and Rebane 2005). Therefore, the solid, dense otoliths of ray-finned fishes should result in a more sensitive ear than the less dense, gelatinous otoliths of sharks including scalloped hammerhead sharks.

Sound is composed of two major components, the propagating sound pressure wave and particle motion. All fishes detect particle motion with their inner ear otoliths (otoconia in elasmobranchs) which act as accelerometers (Casper and Mann 2006). Sound pressure, however, can only be detected by fishes which have a pressure-to-displacement transducer, usually the swim bladder in some teleost fishes (Casper and Mann 2006). Some fishes have evolved a specialized connection between the swim bladder and the inner ear which can transmit the sound pressure signal being detected by the bladder. In the case of the otophysans such as goldfish, modified vertebrae known as the Weberian ossicles have evolved for this function. Scalloped hammerhead sharks (an elasmobranch) and other fishes without swimbladders or any other kind of hearing specialization can only detect the particle motion component of sound (Casper and Mann 2006).

6.4.3.1 Non-impulsive Sound Sources

Studies of the effects of long-duration sounds with sound pressure levels below 170 to 180 dB re 1 µPa indicate that there is little to no effect of long-term exposure on species such as the scalloped hammerhead shark that lack notable anatomical hearing specialization (Amoser and Ladich 2003; Scholik and Yan 2001; Smith et al. 2004a; Smith et al. 2004b; Wysocki et al.

2007). The longest of these studies exposed young rainbow trout (*Onorhynchus mykiss*), to a level of noise equivalent to one that fish would experience in an aquaculture facility (e.g., on the order of 150 dB re 1 µPa) for about 9 months. The investigators found no effect on hearing (i.e., TTS) as compared to fish raised at 110 dB re 1 µPa.

In contrast, studies on fish with hearing specializations (i.e., greater sensitivity to lower sound pressures and higher frequencies) have shown that there is some hearing loss after several days or weeks of exposure to increased background sounds, although the hearing loss seems to recover (e.g., (Scholik and Yan 2002; Smith et al. 2006a; Smith et al. 2004b)). Smith et al. (Smith et al. 2006a; Smith et al. 2004b) exposed goldfish to noise at 170 dB re 1 µPa and found a clear relationship between the amount of hearing loss (TTS) and the duration of exposure until maximum hearing loss occurred after 24 hours of exposure. A 10-minute exposure resulted in a 5 dB TTS, whereas a 3-week exposure resulted in a 28 dB TTS that took over 2 weeks to return to pre-exposure baseline levels (Smith et al. 2004b) (Note: recovery time not measured by investigators for shorter exposure durations).

Similarly, Wysocki and Ladich (2005) investigated the influence of noise exposure on the auditory sensitivity of two freshwater fish with notable hearing specializations, the goldfish and the lined Raphael catfish (*Platydoras costatus*), and on a freshwater fish without notable specializations, the pumpkinseed sunfish (*Lepomis gibbosus*). Baseline thresholds showed greatest hearing sensitivity around 0.5 kHz in the goldfish and catfish and at 0.1 kHz in the sunfish. For the goldfish and catfish, continuous white noise of approximately 130 dB re 1 µPa at 1 m resulted in a significant TTS of 23 to 44 dB. In contrast, the auditory thresholds in the sunfish declined by 7 to 11 dB. The duration of exposure and time to recovery was not addressed in this study. Scholik and Yan (2001) demonstrated TTS in fathead minnows *(Pimephales promelas*) after a 24-hour exposure to white noise (0.3 to 2.0 kHz) at 142 dB re 1 µPa that did not recover as long as 14 days post-exposure.

Studies have also examined the effects of the sound exposures from Surveillance Towed Array Sensor System Low-Frequency Active sonar on fish hearing (Kane et al. 2010; Popper et al. 2007). Hearing was measured both immediately post exposure and for several days thereafter. Maximum received sound pressure levels were 193 dB re 1 µPa for 324 or 628 seconds. Catfish and some specimens of rainbow trout showed 10 to 20 dB of hearing loss immediately after exposure to the low-frequency active sonar when compared to baseline and control animals; however, another group of rainbow trout showed no hearing loss. Recovery in trout took at least 48 hours, but studies were not completed. The different results between rainbow trout groups is difficult to understand, but may be due to developmental or genetic differences in the various groups of fish. Catfish hearing returned to, or close to, normal within about 24 hours after exposure to low-frequency active sonar. Furthermore, examination of the inner ears of the fish during necropsy (note: maximum time fish were held post exposure before sacrifice was 96 hours) revealed no differences from the control groups in cilliary bundles or other features indicative of hearing loss (Kane et al. 2010).

The study of mid-frequency active sonar by the same investigators also examined potential effects on fish hearing and the inner ear (Halvorsen et al. 2012; Kane et al. 2010). Out of the four species tested (rainbow trout, channel catfish, largemouth bass, and yellow perch) only one

group of channel catfish, tested in December, showed any hearing loss after exposure to mid-frequency active sonar. The signal consisted of a 2 second (s) long, 2.8 kHz to 3.8 kHz frequency sweep followed by a 3.3 kHz tone of 1 s duration.

The stimulus was repeated five times with a 25 second interval. The maximum received sound pressure level was 210 dB re 1 µPa. These animals, which have the widest hearing range of any of the species tested, experienced approximately 10 dB of threshold shift that recovered within 24 hours. Channel catfish tested in October did not show any hearing loss. The investigators speculated that the difference in hearing loss between catfish groups might have been due to the difference in water temperature of the lake where all of the testing took place (Seneca Lake, New York) between October and December.

Alternatively, the observed hearing loss differences between the two catfish groups might have been due to differences between the two stocks of fish (Halvorsen et al. 2012). Any effects on hearing in channel catfish due to sound exposure appear to be (Halvorsen et al. 2012; Kane et al. 2010). Investigators observed no damage to cilliary bundles or other features indicative of hearing loss in any of the other fish tested including the catfish tested in October (Kane et al. 2010). Some studies have suggested that there may be some loss of sensory hair cells due to high intensity sources; however, none of these studies concurrently investigated effects on hearing. Enger (1981) found loss of cilliary bundles of the sensory cells in the inner ears of Atlantic cod following 1 to 5 hours of exposure to pure tone sounds between 50 and 400 Hz with a sound pressure level of 180 dB re 1 µPa.

Hastings (1995) found auditory hair-cell damage in a species with notable anatomical hearing specializations, the goldfish (*Carassius auratus*) exposed to 250 Hz and 500 Hz continuous tones with maximum peak levels of 204 dB re 1 µPa and 197 dB re 1 µPa, respectively, for about 2 hours. Similarly, Hastings et al. (1996) demonstrated damage to some sensory hair cells in oscars (*Astronotus ocellatus*) following a 1-hour exposure to a pure tone at 300 Hz with a peak pressure level of 180 dB re 1 µPa. In none of the studies was the hair cell loss more than a relatively small percent (less than a maximum of 15 percent) of the total sensory hair cells in the hearing organs.

In his sounds exposure guidelines for fishes, Popper et al. (2014) estimate exposure to low frequency sonar > 193 dB_{rms} re 1 µPa may lead to TTS in bony fish. The authors were not able to estimate a sound exposure level for mid-frequency sonar at which they would expect TTS. As discussed above, studies of the effects of long-duration sounds with sound pressure levels below 170 to 180 dB re 1 µPa indicate that there is little to no effect of long-term exposure on species such as the scalloped hammerhead shark that lack notable anatomical hearing specialization.

6.4.3.2 Explosions and Other Impulsive Sound Sources

Popper et al. (2005) examined the effects of a seismic airgun array on a fish with hearing specializations, the lake chub (*Couesius plumbeus*), and two species that lack notable specializations, the northern pike (*Esox lucius*) and the broad whitefish (*Coregonus nasus*) (a salmonid). In this study the average received exposure levels were a mean peak pressure level of 207 dB re 1 µPa; sound pressure level of 197 dB re 1 µPa; and single-shot sound exposure level of 177 dB re 1 µPa2-s. The results showed temporary hearing loss for both lake chub and northern pike to both 5 and 20 airgun shots, but not for the broad whitefish. Hearing loss was

approximately 20 to 25 dB at some frequencies for both the northern pike and lake chub, and full recovery of hearing took place within 18 hours after sound exposure. Examination of the sensory surfaces of the ears by an expert on fish inner ear structure showed no damage to sensory hair cells in any of the fish from these exposures (Song et al. 2008).

McCauley et al. (2003) showed loss of a small percent of sensory hair cells in the inner ear of the pink snapper (*Pagrus auratus*) exposed to a moving airgun array for 1.5 hours. Maximum received levels exceeded 180 dB re 1 μPa2-s for a few shots. The loss of sensory hair cells continued to increase for up to at least 58 days post exposure to 2.7 percent of the total cells. It is not known if this hair cell loss would result in hearing loss since fish have tens or even hundreds of thousands of sensory hair cells in the inner ear (Lombarte and Popper 1994; Popper and Hoxter 1984) and only a small portion were affected by the sound. The question remains as to why McCauley et al. (2003) found damage to sensory hair cells while Popper et al. (2005) did not. There are many differences between the studies, including species, precise sound source, and spectrum of the sound that it is hard to speculate.

Hastings et al. (2008) exposed the pinecone soldierfish (*Myripristis murdjan*), a fish with anatomical specializations to enhance their hearing; and three species without notable specializations: the blue green damselfish (*Chromis viridis*), the saber squirrelfish (*Sargocentron spiniferum*), and the bluestripe seaperch (*Lutjanus kasmira*) to an airgun array. Fish in cages in 16 ft. (4.9 m) of water were exposed to multiple airgun shots with a cumulative sound exposure level of 190 dB re 1 μPa2-s. The authors found no hearing loss in any fish following exposures.

In his sound exposure guidelines for fishes, Popper et al. (2014) was not able to develop specific criteria (i.e., sound pressure levels that would result in an impact) for sound exposure from explosions that would lead to PTS, TTS, or behavioral responses. However, the authors did indicate that that individuals realtively close to the source would have a higher relative risk of being impacted than individuals further away.

6.4.4 Auditory Masking

Auditory masking refers to the presence of a noise that interferes with a fish's ability to hear biologically relevant sounds. Fish use sounds to detect predators and prey, and for schooling, mating, and navigating, among other uses (Myrberg Jr. 1980; Popper et al. 2003). Masking of sounds associated with these behaviors could have impacts to fish by reducing their ability to perform these biological functions.

Any noise (i.e., unwanted or irrelevant sound, often of an anthropogenic nature) detectable by a fish can prevent the fish from hearing biologically important sounds including those produced by prey or predators (Myrberg Jr. 1980; Popper et al. 2003). Auditory masking may take place whenever the noise level heard by a fish exceeds ambient noise levels, the animal's hearing threshold, and the level of a biologically relevant sound. Masking is found among all vertebrate groups, and the auditory system in all vertebrates, including fish, is capable of limiting the effects of masking noise, especially when the frequency range of the noise and biologically relevant signal differ (Fay 1988; Fay and Simmons 1999).

The frequency of the sound is an important consideration for fish because many marine fish are limited to detection of the particle motion component of low frequency sounds at relatively high sound intensities (Amoser and Ladich 2005). The frequency of the acoustic stimuli must first be compared to the animal's known or suspected hearing sensitivity to establish if the animal can potentially detect the sound.

One of the problems with existing fish auditory masking data is that the bulk of the studies have been done with goldfish, a freshwater fish with well-developed anatomical specializations that enhance hearing abilities. The data on other species are much less extensive. As a result, less is known about masking in marine species, many of which lack the notable anatomical hearing specializations. However, Wysocki and Ladich (2005) suggest that ambient sound regimes may limit acoustic communication and orientation, especially in animals with notable hearing specializations.

Tavolga studied the effects of noise on pure-tone detection in two species without notable anatomical hearing specializations, the pin fish (Lagodon rhomboids) and the African mouth-breeder (Tilapia macrocephala), and found that the masking effect was generally a linear function of masking level, independent of frequency (Tavolga 1974a; Tavolga 1974b). In addition, Buerkle studied five frequency bandwidths for Atlantic cod in the 20 to 340 Hz region and showed masking across all hearing ranges (Buerkle 1968; Buerkle 1969). Chapman and Hawkins (1973) found that ambient noise at higher sea states in the ocean has masking effects in cod, *Gadus morhua* (L.), haddock, *Melanogrammus aeglefinus* (L.), and pollock, *Pollochinus pollachinus* (L.), and similar results were suggested for several sciaenid species by Ramcharitar and Popper (2004). Thus, based on limited data, it appears that for fish, as for mammals, masking may be most problematic in the frequency region near the signal. There have been a few field studies that may suggest masking could have an impact on wild fish.

Gannon et al. (2005) showed that bottlenose dolphins (*Tursiops truncatus*) move toward acoustic playbacks of the vocalization of Gulf toadfish (*Opsanus beta*). Bottlenose dolphins employ a variety of vocalizations during social communication including low-frequency pops. Toadfish may be able to best detect the low-frequency pops since their hearing is best below 1 kHz, and there is some indication that toadfish have reduced levels of calling when bottlenose dolphins approach (Remage-Healey et al. 2006). Silver perch have also been shown to decrease calls when exposed to playbacks of dolphin whistles mixed with other biological sounds (Luczkovich et al. 2000). Results of the Luczkovich et al. (2000) study, however, must be viewed with caution because it is not clear what sound may have elicited the silver perch response (Ramcharitar et al. 2006). Astrup (1999) and Mann et al. (1998) hypothesized that high frequency detecting species (e.g., clupeids) may have developed sensitivity to high frequency sounds to avoid predation by odontocetes. Therefore, the presence of masking noise may hinder a fish's ability to detect predators and therefore increase predation.

Of considerable concern is that human-generated sounds could mask the ability of fish to use communication sounds, especially when the fish are communicating over some distance. In effect, the masking sound may limit the distance over which fish can communicate, thereby having an impact on important components of their behavior. For example, the sciaenids, which are primarily inshore species, are one of the most active sound producers among fish, and the

sounds produced by males are used to "call" females to breeding sights (Ramcharitar et al. 2001) reviewed in Ramcharitar et al. (2006). If the females are not able to hear the reproductive sounds of the males, there could be a significant impact on the reproductive success of a population of sciaenids. Since most sound production in fish used for communication is generally below 500 Hz (Slabbekoorn et al. 2010), sources with significant low-frequency acoustic energy could affect communication in fish.

Also potentially vulnerable to masking is navigation by larval fish, although the data to support such an idea are still exceedingly limited. There is indication that larvae of some reef fish (species not identified in study) may have the potential to navigate to juvenile and adult habitat by listening for sounds emitted from a reef (either due to animal sounds or non-biological sources such as surf action)(e.g., (Higgs 2005)).

In a study of an Australian reef system, the sound signature emitted from fish choruses was between 0.8 and 1.6 kHz (Cato 1978) and could be detected by hydrophones 3 to 4 nm from the reef (McCauley and Cato 2000). This bandwidth is within the detectable bandwidth of adults and larvae of the few species of reef fish, such as the damselfish, *Pomacentrus partitus*, and bicolor damselfish, *Eupomacentrus partitus*, that have been studied (Kenyon 1996; Myrberg Jr. 1980). At the same time, it has not been demonstrated conclusively that sound, or sound alone, is an attractant of larval fish to a reef, and the number of species tested has been very limited. Moreover, there is also evidence that larval fish may be using other kinds of sensory cues, such as chemical signals, instead of, or alongside of, sound (Atema et al. 2002).

Popper et al. (2014) evaluated the potential for masking in fishes and concluded there is no reason to expect masking from explosions because while the detection of biologically important sounds would be reduced, this effect would only occur during the brief duration of the sound. The authors did not find any data on masking by sonar in fishes, but concluded that if it were to occur, it would only occur during the sonar transmissions and would result in a narrow range of frequencies being masked (Popper et al. 2014).

6.4.5 Physiological Stress

As with masking, a fish must first be able to detect a sound above its hearing threshold for that particular frequency and the ambient noise before a behavioral reaction or physiological stress can occur.

Stress refers to biochemical and physiological responses to increases in background sound. The initial response to an acute stimulus is a rapid release of stress hormones into the circulatory system, which may cause other responses such as elevated heart rate and blood chemistry changes. Although an increase in background sound has been shown to cause stress in humans, only a limited number of studies have measured biochemical responses by fish to acoustic stress (Remage-Healey et al. 2006; Smith et al. 2004; Wysocki et al. 2007) (Wysocki et al. 2006) and the results have varied. There is evidence that a sudden increase in sound pressure level or an increase in background noise levels can increase stress levels in fish (Popper and Hastings 2009a, 2009b). Exposure to acoustic energy has been shown to cause a change in hormone levels (physiological stress) and altered behavior in some species such as the goldfish *(Carassius*

auratus) (Pickering 1981; Smith et al. 2004a, b), but not all species tested to date, such as the rainbow trout *(Oncorhynchus mykiss*) (Wysocki et al. 2007).

Remage-Healey et al. (2006) found elevated cortisol levels, a stress hormone, in Gulf toadfish exposed to low frequency bottlenose dolphin sounds. Additionally, the toadfish' call rates dropped by about 50 percent, presumably because the calls of the toadfish, a primary prey for bottlenose dolphins, give away the fish's location to the dolphin. The researchers observed none of these effects in toadfish exposed to an ambient control sound (i.e., low-frequency snapping shrimp 'pops').

Smith et al. (2004b) found no increase in corticosteroid, a stress hormone, in goldfish exposed to a continuous, band-limited noise (0.1 to 10 kHz) with a sound pressure level of 170 dB re 1 µPa for 1 month. Wysocki et al. (2007) exposed rainbow trout to continuous band-limited noise with a sound pressure level of about 150 dB re 1 µPa for 9 months with no observed stress effects. Growth rates and effects on the trout's immune system were not significantly different from control animals held at sound pressure level of 110 dB re 1 µPa.

6.4.6 Behavioral Reactions

There are little data available on the behavioral reactions of fish, and almost no research conducted on any long-term behavioral effects or the potential cumulative effects from repeated exposures to loud sounds (Popper and Hastings 2009a, 2009b). Behavioral effects to fish could include disruption or alteration of natural activities such as swimming, schooling, feeding, breeding, and migrating. Sudden changes in sound level can cause fish to dive, rise, or change swimming direction. There is a lack of studies that have investigated the behavioral reactions of unrestrained fish to anthropogenic sound, especially in the natural environment. Studies of caged fish have identified three basic behavioral reactions to sound: startle, alarm, and avoidance (McCauley et al. 2000; Pearson et al. 1992). Changes in sound intensity may be more important to a fish's behavior than the maximum sound level. Sounds that fluctuate in level tend to elicit stronger responses from fish than even stronger sounds with a continuous level (Schwartz 1985).

6.4.6.1 Non-impulsive Sound Sources

Gearin et al. (2000) studied responses of adult sockeye salmon (*Oncorhynchus nerka*) and sturgeon (*Acipenser* sp.) to pinger sounds produced by acoustic devices designed to deter marine mammals from gillnet fisheries. The pingers produced sounds with broadband energy with peaks at 2 kHz or 20 kHz. They found that fish did not exhibit any reaction or behavior change to the pingers, which demonstrated that the alarm was either inaudible to the salmon and sturgeon, or that neither species was disturbed by the mid-frequency sound (Gearin et al. 2000). Based on hearing threshold data, it is highly likely that the salmonids did not hear the sounds.

Culik et al. (2001) did a very limited number of experiments to determine the catch rate of herring in the presence of pingers producing sounds that overlapped with the frequency range of hearing for herring (2.7 kHz to over 160 kHz). They found no change in catch rates in gill nets with or without the higher frequency (greater than 20 kHz) sounds present, although there was an increase in the catch rate with the signals from 2.7 kHz to 19 kHz (a different source than the higher frequency source). The results could mean that the fish did not "pay attention" to the higher frequency sound or that they did not hear it, but that lower frequency sounds may be

attractive to fish. At the same time, it should be noted that there were no behavioral observations on the fish, and so how the fish actually responded when they detected the sound is not known.

Doksaeter et al. (2009) studied the reactions of wild, overwintering herring to Royal Netherlands Navy experimental mid-frequency active sonar and killer whale feeding sounds. The behavior of the fish was monitored using upward looking echosounders. The received levels from the 1 to2 kHz and 6 to 7 kHz sonar signals ranged from 127 to 197 dB re 1 µPa and 139 to 209 dB re 1 µPa, respectively. Escape reactions were not observed upon the presentation of the mid-frequency active sonar signals; however, the playback of the killer whale sounds elicited an avoidance reaction. The authors concluded that mid-frequency sonar could be used in areas of overwintering herring without substantially affecting the fish.

There is evidence that elasmobranchs respond to human-generated sounds. Myrberg and colleagues did experiments in which they played back sounds and attracted a number of different shark species to the sound source (Myrberg et al. 1969; Myrberg et al. 1976; Myrberg et al. 1972; Nelson and Johnson 1972). The results of these studies showed that sharks were attracted to low-frequency sounds (below several hundred Hz), in the same frequency range of sounds that might be produced by struggling prey.

However, sharks are not known to be attracted by continuous signals or higher frequencies (which they presumably cannot hear). Studies documenting behavioral responses of fish to vessels show that Barents Sea capelin (*Mallotus villosus*) may exhibit avoidance responses to engine noise, sonar, depth finders, and fish finders (Jørgensen et al. 2004). Avoidance reactions are quite variable depending on the type of fish, its life history stage, behavior, time of day, and the sound propagation characteristics of the water (Schwartz 1985). Misund (1997) found that fish ahead of a ship that showed avoidance reactions did so at ranges of 160 to 490 ft. (48.8 to 149.4 m). When the vessel passed over them, some species of fish responded with sudden escape responses that included lateral avoidance or downward compression of the school.

In a study by Chapman and Hawkins (1973) the low-frequency sounds of large vessels or accelerating small vessels caused avoidance responses by herring. Avoidance ended within 10 seconds after the vessel departed. Twenty-five percent of the fish groups habituated to the sound of the large vessel and 75 percent of the responsive fish groups habituated to the sound of small boats.

Popper et al. (2014) concluded that the relative risk of a fish illiciting a behavioral reaction in response to low-frequency sonar was low, regardless of the distance from the sound source. The authors expected a limited number of species may respond to mid-frequency sonar since most fish do not have specializations that enable them to hear above 2,500 Hz (Popper et al. 2014, Halvorsen et al 2012).

6.4.6.2 Explosions and Other Impulsive Sound Sources

Pearson et al. (1992) exposed several species of rockfish (*Sebastes spp.*) to a seismic airgun. The investigators placed the rockfish in field enclosures and observed the fish's behavior while firing the airgun at various distances for 10 minute trials. Dependent upon the species, rockfish exhibited startle or alarm reactions between peak to peak sound pressure level of 180 dB re 1 µPa

and 205 dB re 1 µPa. The authors reported the general sound level where behavioral alterations became evident was at about 161 dB re 1 µPa for all species. During all of the observations, the initial behavioral responses only lasted for a few minutes, ceasing before the end of the 10-minute trial.

Similarly, Skalski et al. (1992) showed a 52 percent decrease in rockfish (*Sebastes* sp.) caught with hook-and-line (as part of the study—fisheries independent) when the area of catch was exposed to a single airgun emission at 186 to 191 dB re 1 µPa (mean peak level) (See also (Pearson et al. 1987; Pearson et al. 1992)). They also demonstrated that fish would show a startle response to sounds as low as 160 dB re 1 µPa, but this level of sound did not appear to elicit decline in catch. Wright (1982) also observed changes in fish behavior as a result of the sound produced by an explosion, with effects intensified in areas of hard substrate.

Wardle et al. (2001) used a video system to examine the behaviors of fish and invertebrates on reefs in response to emissions from seismic airguns. The researchers carefully calibrated the airguns to have a peak level of 210 dB re 1 µPa at 16 m and 195 dB re 1 µPa at 109 m from the source. There was no indication of any observed damage to the marine organisms. They found no substantial or permanent changes in the behavior of the fish or invertebrates on the reef throughout the course of the study, and no marine organisms appeared to leave the reef.

Engås et al. (1996) and Engås and Løkkeborg (2002) examined movement of fish during and after a seismic airgun study by measuring catch rates of haddock (*Melanogrammus aeglefinus*) and Atlantic cod as an indicator of fish behavior using both trawls and long-lines as part of the experiment. These investigators found a significant decline in catch of both species that lasted for several days after termination of airgun use. Catch rate subsequently returned to normal. The conclusion reached by the investigators was that the decline in catch rate resulted from the fish moving away from the airgun sounds at the fishing site. However, the investigators did not actually observe behavior, and it is possible that the fish just changed depth.

The same research group showed, more recently, parallel results for several additional pelagic species including blue whiting and Norwegian spring spawning herring (Slotte et al. 2004). However, unlike earlier studies from this group, the researchers used fishing sonar to observe behavior of the local fish schools. They reported that fish in the area of the airguns appeared to go to greater depths after the airgun exposure compared to their vertical position prior to the airgun usage. Moreover, the abundance of animals 18 to 31 miles (29 to 50 km) away from the ensonification increased, suggesting that migrating fish would not enter the zone of seismic activity.

Alteration in natural behavior patterns due to exposure to impulsive noise (such as pile driving and explosions) has not been well studied. However, one study (Mueller-Blenkle et al. 2010), which took place with fish enclosed in a mesocosm (an enclosure providing a limited body of water with close to natural conditions), demonstrated behavioral reactions of cod and Dover sole (*Solea solea*) to impulsive sounds from pile driving. Sole showed a significant increase in swimming speed. Cod reacted, but not significantly, and both species showed directed movement away from the sources with signs of habituation after multiple exposures. For sole, reactions were seen with peak sound pressure levels of 144 to 156 dB re 1 µPa; and cod showed altered

behavior at peak sound pressure levels of 140 to 161 dB re 1 µPa. For both species, this corresponds to a peak particle motion between $6.51x10^{-3}$ and $8.62x10^{-4}$ meters per second squared (m/s^2).

Popper et al. (2014) indicated very little is known about the effects of explosions of wild fish behavior, but suggested that startle responses, likely lasting less than a second, could occur from exposure to explosives and that such responses would not necessarily result in significant changes to subsequent behavior.

6.4.7 Repeated Exposures of Fish

As noted previously, there is almost no research on any long-term behavioral effects or the potential cumulative effects from repeated exposures of fish to loud sounds (Popper and Hastings 2009a, 2009b). Assessing the effects of sounds, both individually and cumulatively, on marine species is difficult because responses depend on a variety of factors incuding age class, prior experience, behavioral state at the time of exposure, and indirect effects. Responses may be also be influenced by other non-sound related factors (Ellison et al. 2011; Goldbogen et al. 2013; Kight and Swaddle 2011; McGregor 2013; Williams et al. 2014) (Read et al. 2014). Within the ocean environment, aggregate anthropogenic impacts have to be considered in context of natural variation and climate change (Boyd and Hutchins 2012). To address aggregate impacts and responses from any changes due to processes such as habituation, tolerance, and sensitization, future experiments over an extended period of time still need further research (Bejder et al. 2009; Blickley et al. 2012) (Read et al. 2014).

Most of the scalloped hammerhead sharks that may be exposed to acoustic stressors would be exposed periodically or episodically over certain months or seasons when the Navy is training in the MITT Study Area. The majority of the proposed training and testing activities occur over a small spatial scale relative to the entire Action Area, have few participants, and are of a short duration (the order of a few hours or less). These periodic or episodic exposure and response scenarios most often allow sufficient time to return to baseline conditions and resumption of normal behavioral activities such as feeding and breeding. For example, Navy sonar systems are generally deployed from highly mobile vessels or in-water devices which do not directly target ESA-listed resources. A typical Navy vessel with hull mounted MFA sonar would travel over 0.3 kilometers between pings (based on a speed of 10 knots/hr and transmission rate of 1 ping/min) (Navy 2013). Based on this distance traveled and potential avoidance behavior of acoustically exposed animals, we expect repeat acoustic exposures capable of eliciting a behavioral response to an individual over a brief period of time to be rare. For sonar devices that are stationary (e.g. dipped sonar), due to the duty cycle, duration of active transmission in a specific location, and mitigation measures (e.g. avoidance of visible ESA-listed resources), we would not expect repeated exposures.

Repeated exposure to impulsive acoustic stressors may be more likely as successive detonations could occur in close proximity to one another. However, with the exception of those individuals that are close enough to be killed or seriously injured, we would expect the effect of repeated expsoures under this scenario to not impact the fitness of individual sharks. For example, anecdotal evidence indicates scalloped hammerhead sharks, particularly juveniles, may spend a considerable amount of time in Apra Harbor, a relatively small area where underwater

detonations are expected to occur. As suggested by Popper et al. (2014), most responses to detonations are expected to be temporary startle responses with the animal resuming normal activity shortly after exposure. The same would be expected if multiple startle responses occur resulting from successive detonations. It also may be possible for detonations to temporarily affect juvenile or adult shark refugia or foraging habitat selection. However, given these animal's mobility, we would expect individuals to temporarily select alternative refuge or forage sites nearby until the exposure levels in their initially selected location have decreased. To result in significant fitness consequences we would have to assume that an individual shark could not compensate for lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. Similarly, we would have to assume individuals could not find alternative refuge habitat nearby. There is no indication this is the case. Therefore, even temporary displacement from initially selected habitat is not expected to impact the fitness of any individual animals because we would expect equivalent habitat to be available in close proximity. Further, foraging generally occurs at night, when underwater detonations will not take place, suggesting feeding behavior is not likely to be affected. As noted previously, scalloped hammerhead sharks may also experience hearing loss if an individual is in close proximity to an underwater detonation. However, hearing loss would be temporary because unlike marine mammals, fish are capable of regenerating sensory hairs and no permanent hearing loss has ever been reported in fish (Lombarte et al. 1993) (Smith et al. 2006b). Because we do not expect any fitness consequences from any individual animals, we do not expect any population level effects from these responses.

Multiple stressors may also have synergistic effects. For example, fish that experience temporary hearing loss or injury from acoustic stressors could be more susceptible to physical strike and disturbance stressors via a decreased ability to detect and avoid threats. These interactions are speculative, and without data on the combination of multiple Navy stressors, the synergistic impacts from the combination of Navy stressors are difficult to predict in any meaningful way.

6.5 Delineation of Individuals of *Acropora globiceps*

In the following sections, we provide a summary of the available information used to assess the impacts of the proposed Navy activities on ESA-listed corals. A significant portion of this information is derived from the Final Listing Determinations on Proposal To List 66 Reef-Building Coral Species and To Reclassify Elkhorn and Staghorn Corals (79 FR 53877).

Reef-building corals are clonal organisms. A single larva will develop into a discrete unit (the primary polyp) that then produces modular units (*i.e.*, genetically-identical copies of the primary polyp) of itself, which are connected seamlessly through tissue and skeleton. These modular units may be solitary (*e.g.*, fungiid corals) or colonial. Most reef-building coral species are colonial, including all species covered in the final rule (79 FR 53877). Colony growth is achieved mainly through the addition of more polyps, and colony growth is indeterminate (see Figure 25 for an example of a coral colony). The colony can continue to exist even if numerous polyps die, or if the colony is broken apart or otherwise damaged. The biology of such clonal, colonial species creates ambiguity with regard to delineation of the individual in reef-building corals, specifically: (1) polyps versus colonies; (2) sexually-produced versus asexually-produced colonies; and (3) difficulty determining colony boundaries (79 FR 53877).

Summaries of how NMFS addressed these sources of ambiguity during the listing process are provided below, leading to a conclusion regarding the delineation of the "individual" for the species covered by the final rule.

Figure 25. Example of a Coral Colony, *Acropora globiceps.* (Veron, 2000) Source: (http://www.aims.gov.au/)

The "polyp" could be considered the smallest unit of the individual for reef-building corals. Each polyp in a coral colony consists of a column of tissue with a mouth and tentacles on the upper side, growing in a cup-like skeletal structure (the corallite) made of calcium carbonate that the polyp produces through calcification. The polyps are the building blocks of the colony, and most colony growth occurs by increasing the number of polyps and supporting skeleton. Polyps carry out the biological functions of feeding, calcification, and reproduction. However, because the polyps within a colony are modular units, and connected to one another physiologically (*i.e.*, via nerve net and gastrovascular cavity, and are the same sex), single polyps within a colony were not considered by NMFS to be individuals for purposes of the final listing.

Alternatively, only colonies originating from sexually-produced larvae could be considered as the individual for reef-building corals. Colonies are founded by either sexually-produced larvae that settle and become the primary polyp of a colony, or asexually-produced fragments of pre-existing colonies that break off to form a new colony. Fragments from the same colony can fuse back together into the same colony if they are close enough to grow together. Fragmentation in branching species may lead to a large number of asexually-produced, genetically identical colonies, commonly resulting in a population made up of more asexually-produced colonies than sexually-produced colonies (Hughes 1984). Sexually-produced colonies are important to the population by increasing the genetic diversity of the population, and colonies originating from asexually-produced fragments do not contribute to the effective population (*i.e.*, group of

genetically unique individuals). Asexual reproduction, though it does not create new genetic individuals, is likely the more critical mode for some species, especially branching species, allowing them to grow, occupy space, and persist between relatively rare events of sexual reproduction. Sexually- and asexually-produced colonies often cannot be distinguished from one another in the field, but are identifiable as an individual, in most cases. Thus, NMFS used the concept of the "physiological colony" as the entity considered to be an individual.

The physiological colony for reef-building colonial species is defined as any colony of the species, whether sexually or asexually produced (79 FR 53877). A physiological colony is generally autonomous from other colonies of the same species. However, colony morphology, partial colony mortality, and other colony growth characteristics (*e.g.*, formation of stands or thickets) can complicate the delineation of physiological colonies from one another in the field. In those cases, colony shape may not distinguish colonies from one another, and boundaries between separate encrusting colonies that have grown together may be difficult or impossible to make out visually. Partial mortality of colonies, especially larger colonies, can also mask the boundaries between colonies, because the algae-encrusted coral skeleton of a partially dead colony may appear to delineate two or more colonies. In addition, many reef-building coral species occur in stands or thickets that may be tens of meters or more in diameter (*e.g.*, some *Acropora* species), possibly consisting of multiple colonies or only one large colony, also masking the boundaries between colonies. In each of these instances, the actual number of genetically-distinct individuals can only be determined through genetic analysis.

NMFS' final rule considered the "individual" for each of the proposed species including *Acropora globiceps*, to be the "physiological colony," as defined above. That is, polyps are not considered individuals, but sexually- and asexually-produced colonies are considered individuals because they are a type of physiological colony and are the unit that can be identified in the field.

6.6 Marine Species Density Estimates

Marine mammal and sea turtle density estimates that were used in NAEMO modeling for acoustic effects and our risk analyses on the effects of various stressors from Navy training and testing activities are discussed below. Estimates of abundance or density for corals and scalloped hammerhead shark in the MITT Action Area were not available.

6.6.1 Marine Mammal Density Estimates

Esimates of marine mammal densities from the Pacific NMSDD (See Section 3.4.2) are summarized in Table 46 below.

Table 46. NMSDD Estimates for Marine Mammals in the MITT Action Area and Transit Corridor

Species	Location	Spring	Summer	Fall	Winter
Blue whale	MITT Action Area	0.00001	0.00001	0.00001	0.00001
	Transit Corridore	0.00001	0.00001	0.00001	0.00001
Fin whale	MITT Action Area	0.00001	0.00001	0.00001	0.00001
	Transit	0.00001	0.00001	0.00001	0.00001

	Corridor				
Sei whale	MITT Action Area	0.00029	0	0.00029	0.00029
	Transit Corridor	0.00013	0	0.00013	0.00013
Humpback whale	MITT Action Area	0.00089	0.00089	0.00089	0.00089
	Transit Corridor	0.00089	0.00089	0.00089	0.00089
Sperm whale	MITT Action Area	0.00291	0.00291	0.00291	0.00291
	Transit Corridor	0.00176	0.00176	0.00176	0.00176

The units for numerical values are animals/km2. 0 = species is not expected to be present

6.6.2 Sea Turtle Density Estimates

Species-specific sea turtle density estimates for the MITT Action Area are derived from scientific literature and Navy monitoring and surveying efforts. For more information regarding the specific data sources used to estimate density for each sea turtle species in the MITT Action Area, see the Pacific Navy Marine Species Density Database Technical Report (Hanser et al. 2013).

The species-specific density estimates used in the NAEMO model are detailed in Table 47. For green and hawksbill turtles, available information allowed the Navy to estimate density by geographic location or habitat type (e.g., nearshore Guam, Pelagic and transit corridor, etc). Leatherback and loggerhead are much less common in the MITT Action Area and a low density was assumed to represent the occasional transit of the Action Area. The density values below represent year round estimates. Density estimates by season are not available for sea turtles. For the MITT Action Area, an area was selected along the transit corridor to represent the range of different habitats that could occur along the corridor, including both island (Wake Island) and open ocean habitats. This is referred to as the "Transit Corridor" and assigned specific density estimates.

Table 47. NMSDD Estimates for Sea Turtles in the MITT Action Area and Transit Corridor

Species	Location	Density
Hawksbill	Nearshore FDM	1.0734
	Nearshore other islands	0.1342
	Pelagic and Transit Corridor	0.000024
Green	Nearshore Guam	0.2968
	Nearshore Tinian and other Islands	11.8
	Pelagic and Transit Corridor	0.000391
Loggerhead	MITT Action Area	0.000022
Leatherback	MITT Action Area	0.00022

The units for numerical values are animals/km^2.

6.7 Stressors Not Likely to Adversely Affect ESA-listed Species

The following section discusses stressors that are not likely to adversely affect ESA-listed species. If a stressor is likely to adversely affect any of the ESA-listed species in the MITT Action Area, it is discussed further in Section 6.8 and carried forward in our effects analysis. We address the specific species that are not likely to be adversely affected by respective stressors in those sections.

6.7.1 Effects of Weapons Firing, Launch and Impact Noise

Ship fired munitions can create blast waves from the gun muzzle and along the trajectory of the shell but it is expected the noise will only be detectable to marine mammals, sea turtles, and scalloped hammerhead sharks within a very small footprint along the trajectory. Aircraft fired munitions are not expected to have sound waves emanating from the firing source that would be of sufficient intensity to propogate a sound wave into the water. Non-explosive ordnance can also impact the water with substantial force and produce loud noises but no TTS exposures of ESA-listed marine mammals are predicted from navy modeling efforts. Marine mammals, sea turtles, and scalloped hammerhead sharks within the audible range of munition firing, launching and impact may exhibit a behavioral startle response but are expected to quickly return to normal behavior. Munitions firing, launch, and impacts are sporadic events of short duration reducing the likelihood of subjecting individual marine mammals, sea turtles, or scalloped hammerhead sharks to prolonged or repeated exposures. Due to the short duration and sporadic nature of munition firing, the low likelihood of an ESA-listed animal being within close enough proximity to detect sound from firing above water, and the high likelihood an ESA-listed animal that does detect noise from munition firing would react very briefly, we do not expect an increase in the likelihood of injury from significant disruption of breeding, feeding, or sheltering is expected for ESA-listed marine mammals, sea turtles, or scalloped hammerhead sharks. Therefore, the effects of weapon firing, launching, and impact noise on ESA-listed marine mammals, sea turtles, and scalloped hammerhead sharks would not rise to the level of take and any behavioral impacts would be insignificant.

Corals are not biologically capable of detecting noise except as vibrations of water particles caused by low frequency sounds, therefore effects to ESA-listed corals from noise stressors associated with weapon firing and impacts are not reasonably expected to occur.

6.7.2 Effects of Aircraft Noise

Studies have shown that aircraft presence and operation can result in changes in behavior of cetaceans (Arcangeli and Crosti 2009; Holt et al. 2009; Luksenburg and Parsons 2009; Noren et al. 2009; Patenaude et al. 2002; Richter et al. 2006; Richter et al. 2003; Smultea et al. 2008). Many of the activities the U.S. Navy conducts in the MITT Action Area involve some level of activity from aircraft that include helicopters, maritime patrols, and fighter jets. Low-flying aircraft produce sounds that marine mammals can hear when they occur at or near the ocean's surface. Helicopters generally tend to produce sounds that can be heard at or below the ocean's surface more than fixed-wing aircraft of similar size and larger aircraft tend to be louder than smaller aircraft. Underwater sounds from aircraft are strongest just below the surface and directly under the aircraft. Sounds from aircraft would not have physical effects on marine mammals but represent acoustic stimuli (primarily low-frequency sounds from engines and rotors) that have been reported to affect the behavior of some marine mammals and sea turtles.

We did not estimate the number of endangered or threatened species that are likely to be exposed to noise from aircraft overflight, take-offs and landings from carriers, or other fixed or rotary-wing aircraft operations at altitudes low enough for the sounds to be salient at or immediately below the ocean's surface. Nevertheless, we assume any ESA-listed species that occur in the Action Area during training exercises and testing activities that involve aircraft are likely to be exposed to minor acoustic stimuli associated with aircraft traffic.

There are few studies of the responses of marine animals to air traffic and the few that are available have produced mixed results. Some investigators report responses while others report no responses. Richardson et al. (1995c) reported that there is no evidence that single or occasional aircraft flying above large whales and pinnipeds in-water cause long-term displacement of these mammals. Several authors have reported that sperm whales did not react to fixed-wing aircraft or helicopters in some circumstances (Au and Perryman 1982, Clarke 1956b, Green et al. 1992) (Gambell 1968) and reacted in others (Clarke 1956b, Fritts et al. 1983, Patenaude et al. 2002, Richter et al. 2003, 2006, Smultea et al. 2008, Würsig et al. 1998) (Mullin et al. 1991). Richardson et al. (1985) reported that bowhead whales responded behaviorally to fixed-wing aircraft that were used in their surveys and research studies when the aircraft were less than 457 m above sea level; their reactions were uncommon at 457 m, and were undetectable above 610 meters. They also reported that bowhead whales did not respond behaviorally to helicopter overflights at about 153 m above sea level.

Smultea et al. (2008) studied the response of sperm whales to low-altitude (233 to 269 m) flights by a small fixed-wing airplane near Kaua'i and reviewed data available from other studies. They concluded that sperm whales responded behaviorally to aircraft passes in about 12 percent of encounters. All of the reactions consisted of sudden dives and occurred when the aircraft was less than 360 m from the whales (lateral distance). They concluded that the sperm whales had perceived the aircraft as a predatory stimulus and responded with defensive behavior. In at least

one case, Smultea et al. (2008) reported that the sperm whales formed a semi-circular "fan" formation that was similar to defensive formations reported by other investigators.

In a review of aircraft noise effects on marine mammals, Luksenburg and Parsons (2009) determined that the sensitivity of whales and dolphins to aircraft noise may depend on the animals' behavioral state at the time of exposure (e.g. resting, socializing, foraging or travelling) as well as the altitude and lateral distance of the aircraft to the animals. While resting animals seemed to be disturbed the most, low flying aircraft with close lateral distances over shallow water elicited stronger disturbance responses than higher flying aircraft with greater lateral distances over deeper water (Patenaude et al. 2002, Smultea et al. 2008 in Luksenburg and Parsons (2009).

Based on sea turtle sensory biology (Bartol et al. 1999b; Ketten and Bartol 2005; Ketten and Bartol 2006; Lenhardt et al. 1994a; Ridgway et al. 1969), sound from low flying aircraft could be heard by a sea turtle at or near the surface. Turtles might also detect low flying aircraft via visual cues such as the aircraft's shadow. Hazel et al. (2007) suggested that green turtles rely more on visual cues than auditory cues when reacting to approaching water vessels. This suggests that sea turtles might not respond to aircraft overflights based on noise alone.

Based on limited morphological and scientific study, scalloped hammerhead sharks are likely less sensitive to above-water acoustic noise, such as that originating from aircraft, than marine mammals. Corals are not biologically capable of detecting noise except as vibrations of water particles caused by low frequency sounds, therefore effects to ESA-listed corals from noise stressors are not reasonably expected to occur.

In conclusion, the low number of aircraft flights, typical altitudes of flights, sporadic occurrence of flights, limited duration of flights, and the lack of substantial sound propagation into the water column from aircraft indicates there is a low probability of exposing marine mammals, sea turtles, scalloped hammerhead sharks and corals to aircraft noise at perceivable levels. In the event an ESA-listed species was exposed to aircraft noise, it would likely result in temporary behavioral responses. These behavioral responses would not increase the likelihood of injury from significantly disrupting breeding, feeding, or sheltering and would not rise to the level of take. Therefore, the effects of aircraft noise on ESA-listed species is insignificant and not likely to adversely affect them.

6.7.3 Effects of Vessel Noise

Sounds emitted by large vessels can be characterized as low-frequency, continuous, or tonal, and sound pressure levels at a source will vary according to speed, burden, capacity and length (Richardson et al. 1995c) (Kipple and Gabriele 2007; McKenna et al. 2012). Vessels ranging from 135 to 337 m (Nimitz-class aircraft carriers, for example, have lengths of about 332 m) generate peak source sound levels from 169 to 200 dB between 8 Hz and 430 Hz. Source levels for 593 container ship transits were estimated from long-term acoustic recording received levels in the Santa Barbara shipping channel, and a simple transmission loss model using Automatic Identification System data for source-receiver range (McKenna et al. 2013). Ship noise levels could vary 5 to 10 dB depending on transit conditions. Given the sound propagation of low frequency sounds, a large vessel in this sound range can be heard 139 to 463 km away (Polefka

2004). Hatch et al. (2008) measured commercial ship underwater noise levels and reported average source level estimates (71 to 141 Hz, root-mean-square pressure re 1 uPa ± SE) for individual vessels ranged from 158 ± 2 dB (research vessel) to 186 ± 2 dB (oil tanker). McKenna et al (2012) in a study off Southern California documented different acoustic levels and spectral shapes observed from different modern ship-types.

Numerous studies of interactions between surface vessels and marine mammals have demonstrated that free-ranging marine mammals engage in avoidance behavior when surface vessels move toward them. It is not clear whether these responses are caused by the physical presence of a surface vessel, the underwater noise generated by the vessel, or an interaction between the two (Amaral and Carlson 2005; Au and Green 2000; Bain et al. 2006; Bauer 1986; Bejder et al. 1999; Bejder and Lusseau. 2008; Bejder et al. 2009; Bryant et al. 1984; Corkeron 1995; Erbe 2002b; Félix 2001; Goodwin and Cotton 2004; Lemon et al. 2006; Lusseau 2003; Lusseau 2006; Magalhaes et al. 2002; Nowacek et al. 2001; Richter et al. 2003; Scheidat et al. 2004; Simmonds 2005; Watkins 1986; Williams et al. 2002b; Wursig et al. 1998). However, several authors suggest that the noise generated during motion is probably an important factor (Blane and Jaakson 1994; Evans et al. 1992; Evans et al. 1994). These studies suggest that the behavioral responses of marine mammals to surface vessels are similar to their behavioral responses to predators.

Based on the suite of studies of cetacean behavior to vessel approaches (Au and Perryman 1982; Bain et al. 2006; Bauer and Herman 1986; Bejder et al. 1999; Bejder et al. 2006a; Bejder et al. 2006b; Bryant et al. 1984; Corkeron 1995; David 2002; Felix 2001; Goodwin and Cotton 2004; Hewitt 1985b; Lusseau 2003; Lusseau 2006; Magalhaes et al. 2002; Nowacek et al. 2001; Richter et al. 2006; Richter et al. 2003; Scheidat et al. 2004; Simmonds 2005; Watkins 1986; Williams and Ashe 2007; Williams et al. 2002b; Wursig et al. 1998) (Aguilar Soto et al. 2006; Arcangeli and Crosti 2009; Au and Green 2000; Christiansen et al. 2010; Erbe 2002b; Noren et al. 2009; Stensland and Berggren 2007; Stockin et al. 2008; Williams et al. 2009)(Acevedo 1991), the set of variables that help determine whether marine mammals are likely to be disturbed by surface vessels include:

- *Number of vessels*. The behavioral repertoire marine mammals have used to avoid interactions with surface vessels appears to depend on the number of vessels in their perceptual field (the area within which animals detect acoustic, visual, or other cues) and the animal's assessment of the risks associated with those vessels (the primary index of risk is probably vessel proximity relative to the animal's flight initiation distance) (Sims et al. 2012).

- Below a threshold number of vessels (which probably varies from one species to another, although groups of marine mammals probably share sets of patterns), studies have shown that whales will attempt to avoid an interaction using horizontal avoidance behavior. Above that threshold, studies have shown that marine mammals will tend to avoid interactions using vertical avoidance behavior, although some marine mammals will combine horizontal avoidance behavior with vertical avoidance behavior (Bryant et al.

1984; David 2002; Kruse 1991a; Lusseau 2003; Nowacek et al. 2001; Stensland and Berggren 2007; Williams and Ashe 2007);

- *The distance between vessel and marine mammals* when the animal perceives that an approach has started and during the course of the interaction (Au and Perryman 1982; David 2002; Hewitt 1985b; Kruse 1991a; Lundquist et al. 2012; Lusseau 2003; Tseng et al. 2011);

- *The vessel's speed and vector* (David 2002);

- *The predictability of the vessel's path*. That is, cetaceans are more likely to respond to approaching vessels when vessels stay on a single or predictable path (Acevedo 1991a; Angradi et al. 1993; Browning and Harland. 1999; Lusseau 2003; Lusseau 2006; Williams et al. 2002a) than when it engages in frequent course changes (Evans et al. 1994; Lusseau 2006; Williams et al. 2002a);

- *Noise associated with the vessel* (particularly engine noise) and the rate at which the engine noise increases (which the animal may treat as evidence of the vessel's speed) (David 2002; Lusseau 2003; Lusseau 2006; Polagye et al. 2011);

- *The type of vessel* (displacement versus planing), which marine mammals may be interpret as evidence of a vessel's maneuverability (Goodwin and Cotton 2004);

- *The behavioral state of the marine mammals* (David 2002; Lusseau 2003; Lusseau 2006; Wursig et al. 1998). For example, Würsig et al. (Wursig et al. 1998) concluded that whales were more likely to engage in avoidance responses when the whales were milling or resting than during other behavioral states.

Most of the investigations reported that animals tended to reduce their visibility at the water's surface and move horizontally away from the source of disturbance or adopt erratic swimming strategies (Corkeron 1995; Lundquist et al. 2012; Lusseau 2003; Lusseau 2004; Nowacek et al. 2001; Van Parijs and Corkeron 2001; Williams et al. 2002a; Williams et al. 2002b). In the process, their dive times increased, vocalizations and jumping were reduced (with the exception of beaked whales), individuals in groups move closer together, swimming speeds increased, and their direction of travel took them away from the source of disturbance (Baker and Herman 1989; Edds and Macfarlane 1987; Evans et al. 1992; Kruse 1991a). Some individuals also dove and remained motionless, waiting until the vessel moved past their location. Most animals finding themselves in confined spaces, such as shallow bays, during vessel approaches tended to move towards more open, deeper waters (Kruse 1991a). We assume that this movement would give them greater opportunities to avoid or evade vessels as conditions warranted.

Although most of these studies focused on small cetaceans (for example, bottlenose dolphins, spinner dolphins, spotted dolphins, harbor porpoises, beluga whales, and killer whales), studies

of large whales have reported similar results for fin and sperm whales (David 2002). Baker et al. (1983) reported that humpbacks in Hawaii responded to vessels at distances of 2 to 4 km. Richardson et al. (1985) reported that bowhead whales (*Balaena mysticetus*) swam in the opposite direction of approaching seismic vessels at distances between 1 and 4 km and engage in evasive behavior at distances under 1 km. Fin whales also responded to vessels at a distance of about 1 km (Edds and Macfarlane 1987). A study by Lundquist (2012) on dusky dolphins concluded that repeated disturbance from tour vessel traffic may interrupt social interactions, and postulated that those repeated disturbances may carry energetic costs, or otherwise affect individual fitness. However, they were unable to determine if such disturbances were likely to cause long-term harm. For behavioral responses to result in energetic costs that result in long-term harm, such disturbances would likely need to be sustained for a significant duration or extent where individuals exposed would not be able to select alternate habitat to recover and feed. Typical Navy training and testing activities would not likely result in such prolonged exposures and preclusion of individuals from feeding, breeding, or sheltering habitat.

Würsig et al. (1998) studied the behavior of cetaceans in the northern Gulf of Mexico in response to survey vessels and aircraft. They reported that false killer whales either did not respond or approached the ship (most commonly to ride the bow). Four of 15 sperm whales avoided the ship while the remainder appeared to ignore its approach.

For surface vessels, the set of variables that help determine whether marine mammals are likely to be disturbed include: (1) the number of vessels in a marine mammal's perceptual field and the animal's assessment of the risks associated with those vessels; (2) the distance between vessels and marine mammals; (3) the vessel's speed and path; (4) the predictability of the vessel's path; (5) noise associated with the vessel and the rate at which the engine noise increases; (6) the type of vessel; and (7) the behavioral state of the animal. Because of the number of vessels involved in U.S. Navy training exercises and testing activities, the vessel speed, and the use of course changes as a tactical measure with the associated sounds, the available evidence leads us to expect marine mammals to treat Navy vessels as stressors. Further, without considering differences in sound fields associated with any active sonar that is used during these exercises, the available evidence suggests that major training exercises, unit- and intermediate-level exercises, and testing activities would represent different stress regimes because of differences in the number of vessels involved, vessel maneuvers, and vessel speeds.

We recognize that Navy vessels almost certainly incorporate quieting technologies that reduce their acoustic signature (relative to the acoustic signature of similarly sized vessels) in order to reduce their vulnerability to detection by enemy vessels (Southall 2005). Nevertheless, we do not assume that any quieting technology would be sufficient to prevent marine mammals from detecting sounds produced by approaching Navy vessels and perceiving those sounds as predatory stimuli. We also consider evidence that factors other than received sound level, including the activity state of animals exposed to different sounds, the nature and novelty of a sound, and spatial relations between sound source and receiving animals (i.e., the exposure context) strongly affect the probability of a behavioral response (Ellison et al. 2012).

We considered the research and reports cited above and conclude that ESA-listed marine mammals, sea turtles, and scalloped hammerhead sharks are likely to either not react or exhibit

an avoidance behavior. Most avoidance responses would consist of slow movements away from vessels the animals perceive are on an approaching course, perhaps accompanied by slightly longer dives in marine mammals and turtles. Most of the changes in behavior would consist of a temporary shift from behavioral states that have low energy requirements (resting or milling) to behavioral states with higher energy requirements (active swimming or traveling) and then returning to the resting or milling behavior.

Behavioral disruptions of ESA-listed species resulting from the presence of vessels or submarines are expected to be temporary. Animals are expected to resume their migration, feeding, or other behaviors with no significant impact to their breeding, feeding or sheltering. Marine mammals react to vessels in a variety of ways and seem to be generally influenced by the activity the marine mammal is engaged in when a vessel approaches (Richardson et al. 1995c). Some respond negatively by retreating or engaging in antagonistic responses while other animals ignore the stimulus altogether (Terhune and Verboom 1999; Watkins 1986). Given the short duration of vessel noise stressors, the infrequency of this stressor, and the temporary nature of biological responses of marine mammals, sea turtles and scalloped hammerhead sharks to this stressor, these ESA-listed species are either not likely to respond or are not likely to respond in ways that might be adverse (the responses might represent an approach or attentive movement, a small change in orientation in the waters, etc.).

Corals are not biologically capable of detecting noise except as vibrations of water particles caused by low frequency sounds, therefore effects to ESA-listed corals from noise stressors are not reasonably expected to occur.

In conclusion, ESA-listed species are either not likely to respond to vessel noise or are not likely to measurably respond in ways that would significantly disrupt normal behavior patterns which include, but are not limited to, breeding, feeding or sheltering. Therefore, the effects of noise from Navy vessels on ESA-listed species would not rise to the level of take and is considered insignificant.

6.7.4 Effects of Fiber Optic Cables, Guidance Wires, and Decelarators/Parachutes from Entanglement

Expended materials from U.S. Navy training and testing may pose a risk of entanglement or ingestion to marine mammals and sea turtles in the MITT Action Area. These interactions could occur at the sea surface, in the water column, or on the seafloor. Similar to interactions with other types of marine debris (e.g., fishing gear, plastics), interactions with military expended materials could result in negative sub-lethal effects, mortality, or result in no impact.

Expended materials from Navy training and testing may include the following: fiber optic cables, guidance wires, parachutes, 55 gallon drums, sonobuoy tubes, unrecovered aircraft stores (e.g., fuel tanks, carriages, dispensers, racks), ship hulks, and targets. At-sea targets are usually remotely-operated airborne, surface, or subsurface traveling units, most of which are designed to be recovered for reuse. However, if they are used during activities that utilize high-explosives, they may fragment. Expendable targets that may fragment include air-launched decoys, surface targets (such as marine markers, paraflares, cardboard boxes, and 10 ft. diameter red balloons), and mine shapes. Most expended materials and target fragments are expected to sink quickly to

the seafloor. Floating material, such as Styrofoam, may be lost from target boats and remain at the surface for some time.

There has never been a reported or recorded instance of marine mammals or sea turtles entangled in military expended materials. Though there is a potential for ESA-listed species to encounter military expended material, given the large geographic area involved, and the presumeably low densities of threatened or endangered species in the MITT Action Area, we do not believe such interactions are likely to occur. Additionally, most expended materials are expected to sink upon release, and relatively few ESA-listed animals feed in the deepwater benthic habitats where most expended materials are likely to settle. While disturbance or strike from any expended material as it falls through the water column is possible, it is not likely because the objects will slow in velocity as they sink toward the bottom (e.g., guidance wires sink at an estimated rate of 0.7 ft. [0.2 m] per second), and can be avoided by highly mobile organisms such as marine mammals, sharks, and sea turtles. Bottom feeding animals have an increased likelihood of encountering expended materials because they may find them during feeding long after the training or testing event has occurred. If encountered, foraging animals may ingest the item or become entangled by it.

If encountered, it is unlikely that an animal would get entangled in a fiber optic cable, guidewire, parachute, or other expended material while it was sinking or upon settling to the seafloor. An animal would have to swim through loops or become twisted within the cable or wire to become entangled, and given the properties of the expended cables and wires (low breaking strength and sinking rates) the probability of injury or mortality from expended materials is low. Specifically, fiber optic cable is brittle and would be expected to break if kinked, twisted or sharply bent. Thus, the physical properties of the fiber optic cable would not allow the cable to loop, greatly reducing the likelihood of entanglement of ESA-listed species. Based on degradation times, guidance wires would break down within one to two years and no longer pose an entanglement risk. The length of the guidance wires vary, but greater lengths increase the likelihood that a marine mammal or sea turtle could become entangled. Parachutes used by the Navy range in size from 18 to 48 in. (46 to 122 cm), but the vast majority of expended decelerator/parachutes are small (18 in.) cruciform shaped decelerators used with sonobuoys. They have short attachment lines and, upon water impact, may remain at the surface for 5 to 15 seconds before the decelerator/parachute and its housing sink to the seafloor. Entanglement of an animal in a parachute assembly at the surface or within the water column would be unlikely, since the parachute would have to land directly on an animal, or an animal would have to swim into it before it sinks. It is possible that a bottom feeding animal (e.g., sperm whale, sea turtle) could become entangled when they are foraging in areas where parachutes have settled on the seafloor. For example, if bottom currents are present, the canopy may temporarily billow and pose a greater entanglement threat. However, the likelihood of curents causing a billowing of a parachute and being encountered by an ESA-listed species is so unlikely as to be considered discountable. Fiber optic cables, guidance wires, and decelarators/parachutes will be used over deep water, reducing the likelihood of settling on coral reefs and ESA-listed corals. It is not reasonably predicted ESA-listed corals will be exposed to these items.

In conclusion, based on their deep-water location of use, their sinking rate, their degredation rate, and the presumably low density of ESA-listed species, the likelihood of ESA-listed species

becoming entangled in expended materials is so low as to be discountable. Therefore, entanglement is not likely to adversely affect ESA-listed species.

6.7.5 Effects of Munitions and Other Military Expended Materials from Ingestion

The only munitions and other materials small enough to be ingested by ESA-listed marine mammals, sea turtles, and scalloped hammerhead sharks are small- and medium-caliber projectiles, broken pieces of firing targets, chaff, flare caps, decelerators/parachutes, and shrapnel fragments from explosive ordnance. Most expendable materials will be used over deep water and these items will sink quickly and settle on the seafloor with the exception of chaff and some firing target materials. Given the limited time most items will spend in the water column it is not reasonably expected these items will be accidentally ingested by ESA-listed species not accustomed to foraging on the sea floor. The ESA-listed species potentially exposed to expended munitions and shrapnel fragments while foraging on the sea floor is limited to sperm whales, sea turtles, and the scalloped hammerhead shark. Although scalloped hammerhead sharks and green, loggerhead, and hawksbill sea turtles are known to forage along the sea floor they are restricted to doing so in relatively shallow, near shore areas where expendable material use is not normally conducted. In contrast, sperm whales are capable of foraging along the sea floor in deep water. However, the relatively low density of both sperm whales and expended materials along the vast sea floor suggests ingestion would be rare. In cases where sperm whales, sea turtles, and scalloped hammerhead sharks do accidentally ingest expended materials small enough to be eaten it is likely they will pass through the digestive tract and not result in an increased likelihood of injury from significant disruption of breeding, feeding, or sheltering. ESA-listed corals are likely not capable of ingesting expended materials due to their size and their exposure would be limited due to corals primarily existing in near shore areas. Therefore, ingestion of expended materials by corals is not reasonably expected to occur.

Chaff is composed of fine fibers of silicon dioxide coated with aluminum alloy. Due to their light weight and small size they float and can be carried great distances in both air and water currents. Their dispersal in wind and water results in chaff fibers likely occur in low densities on the ocean surface. Given the small size, low densities, and low toxicity of chaff, any accidental ingestion by ESA-listed species feeding at the ocean surface is not expected to result in an increased likelihood of injury from significant disruption of breeding, feeding, or sheltering. Firing target materials are normally retrieved before sinking and it is not reasonable to expect ingestion of these items to occur.

In conclusion, ESA-listed species are either so unlikely to ingest expended material as to be discountable, or in the case of bottom-feeding species, any ingested materials are likely to pass through the digestive tract without causing injury or any effects rising to the level of take. Therefore, the effects of ingested expended materials on ESA-listed species is either discountable, or insignificant, and not likely to adversely affect them.

6.7.6 Effects of Electromagnetic Devices

Normandeau et al. (Normandeau et al. 2011) concluded there was behavioral, anatomical, and theoretical evidence indicating cetaceans sense magnetic fields. Most of the evidence in this regard is indirect evidence from correlation of sighting and stranding locations suggesting that cetaceans may be influenced by local variation in the earth's magnetic field (Kirschvink 1990)

(Klinowska 1985) (Walker et al. 1992). Results from one study in particular showed that long-finned and short-finned pilot whales, striped dolphin, Atlantic spotted dolphin, Atlantic white-sided dolphin, fin whale, common dolphin, harbor porpoise, sperm whale, and pygmy sperm whale were found to strand in areas where the earth's magnetic field was locally weaker than surrounding areas (negative magnetic anomaly) (Kirschvink 1990). Results also indicated that certain species may be able to detect total intensity changes of only 0.05 microtesla (Kirschvink et al. 1986). This gives insight into what changes in intensity levels some species are capable of detecting, but does not provide experimental evidence of levels to which animals may physiologically or behaviorally respond. Further,not all physiological or behavioral responses are biologically significant and rise to the level of take as defined in the ESA.

Impacts to marine mammals associated with electromagnetic fields are dependent on the animal's proximity to the source and the strength of the magnetic field. Electromagnetic fields associated with naval training exercises and testing activities are relatively weak (only 10 percent of the earth's magnetic field at 79 ft.), temporary, and localized. Once the source is turned off or moves from the location, the electromagnetic field is gone. A marine mammal would have to be present within the electromagnetic field (approximately 656 ft. [200 m] from the source) during the activity in order to detect it. Again, detection does not necessarily signify a significant biological response rising to the level of take as defined under the ESA. Given the small area associated with mine fields, the infrequency and short duration of magnetic energy use, the low intensity of electromagnetic energy sources, and the density of cetaceans in these areas, the likelihood of ESA-listed cetaceans being exposed to electromagnetic energy at sufficient intensities to create a biologically relevant response is so low as to be discountable. Therefore, electromagnetic energy from mine neutralization equipment is not likely to adversely affect ESA-listed cetaceans and will not be considered further in this Opinion.

Sea turtles use geomagnetic fields to navigate at sea, and therefore changes in those fields could impact their movement patterns (Lohmann and Lohmann 1996a) (Lohmann and Lohmann 1996b) (Lohmann et al. 1997). Turtles in all life stages orient to the earth's magnetic field to position themselves in oceanic currents; this helps them locate seasonal feeding and breeding grounds and to return to their nesting sites (Lohmann and Lohmann 1996a) (Lohmann and Lohmann 1996b) (Lohmann et al. 1997). Experiments show that sea turtles can detect changes in magnetic fields, which may cause them to deviate from their original direction (Lohmann and Lohmann 1996a) (Lohmann and Lohmann 1996b) Lohmann et al. 1997). For example, Lohmann and Lohmann (Lohmann and Lohmann 1996a) (Lohmann and Lohmann 1996b) found that loggerhead hatchlings tested in a magnetic field of 52,000 nanoteslas (nT) swam eastward, and when the field was decreased to 43,000 nT, the hatchlings swam westward. Sea turtles also use nonmagnetic cues for navigation and migration, and these additional cues may compensate for variations in magnetic fields. Experimental studies show that hatchlings and juvenile turtles are sensitive to the earth's natural magnetic field and they can distinguish magnetic inclination in different places during their migration routes (Lohmann 1991) (Luschi et al. 2007). Sea turtles can distinguish magnetic differences lighter than 9 milliteslas (or 9,000 microteslas (μT)) (Lohmann et al. 1999) (Lohmann et al. 2001).

If located in the immediate area (within about 650 ft. [200 m]) where electromagnetic devices are being used, sea turtles could deviate from their original movements. Even if detectable, the

electromagnetic devices used in training exercises and testing activities are not expected to cause more than a short-term behavioral disturbance to sea turtles because of the: (1) relatively low intensity of the magnetic fields generated (0.2 μT [or 200 nT] at 200 m [656.2 ft.] from the source), (2) very localized potential impact area, and (3) temporary duration of the activities (hours). Impacts of exposure to electromagnetic stressors are not expected to result in substantial changes to an individual's behavior, growth, survival, annual reproductive success, lifetime reproductive success (fitness), or species recruitment, and are not expected to result in population-level impacts. Therefore, the effects of electromagnetic energy from mine neutralization equipment are insignificant and not likely to adversely affect ESA-listed sea turtles.

In a recent literature review on the effects of electromagnetic fields on marine species (Fisher and Slater 2010) elasmobranchs including scalloped hammerhead sharkes were noted to have extreme sensitivity to low-frequency AC electric fields but little is known about their sensitivity to magnetic fields. Elasmobranchs, scalloped hammerhead sharks use natural electromagnetic fields in their daily lives and, as a result, are at a higher risk of influence from anthropogenic sources . These species receive electrical information about the positions of their prey, the drift of ocean currents, and their magnetic compass headings. In general, elasmobranchs experience sensitivity to E-fields between 5 x 10-7 to 10-3 V/m (Fisher and Slater 2010). At this level, these species are generally attracted to the source; however, at 1 μV/cm or greater, elasmobranchs typically avoid the source (Kalmijn 1982) (Gill and Taylor 2002). However, there are discrepancies between the findings of Gill and Taylor (2002) and Kalmijn (1982) on the lower threshold for elasmobranchs sensitivity to E-fields. Gill and Taylor report this threshold at 5 x 10-7 V/m, while Kalmijn reports it to be 5 x 10-9 V/m. Elasmobranchs attacking submarine cables has been observed (Marra 1989). In 1982, off the coast of Massachusetts, an experiment determined the sensitivity of dogfish (*Mustelus canis*), stingray (*Urolophus halleri*), and blue shark (*P. glauca*) to E-fields. Each species attacked the Efield sources (Kalmijn 1982).

A CMACS (2003) discussion indicated that the strength of the electromagnetic fields emitted by submerged AC cables are substantially lower than those associated with the Earth's geomagnetic field. Therefore, they may be undetectable to magneto-sensitive species, such as scalloped hammerhead sharks, that are attuned to naturally occurring field strengths. While some elasmobranch species such as sharks can detect and respond to electromagnetic fields that are within the range induced by submerged power cables and other anthropogenic sources, no studies were found describing whether such levels affect the behavior of elasmobranchs under field conditions (Fisher and Slater 2010). We assume that scalloped hammerhead sharks most likely avoid sources of strong electromagnetic fields and that any potetial behavioral responses would be very minor and only occur very near the source. Therefore, we conclude that scalloped hammerhead sharks are not likely to be adversely affected by electromagnetic devices during Navy training and testing activities.

Reef-building corals grown in an electromagnetic field generally have higher growth rates and less mortality as shown by experimental studies with *Acropora pulchra* and *Acropora yongei* (Borell et al. 2010). Electromagnetic fields presumeably aid in the accretion of calcium carbonate, allowing reef building corals to grow at a faster rate. ESA-listed corals are not

expected to experience negative effects from the use of electromagnetic devices and any effects may be beneficial.

6.7.7 Effects of In-water Devices from direct physical strikes

Despite thousands of Navy exercises in which torpedoes and in-water devices (unmanned surface vehicles, unmanned undersea vehicles, towed devices) have been used there have been no recorded instances of marine species strikes. Therefore, the likelihood of striking a marine mammal, sea turtle, or scalloped hammerhead shark is so unlikely as to be discountable. Any ESA-listed marine mammal, sea turtle, or shark species is likely to exhibit behavioral avoidance of in-water devices in the event they are within range to detect them. Any such avoidance behavior would be of short duration and intensity that it will not increase the likelihood of injury from disruption of breeding, feeding, or sheltering and would not rise to the level of take. The likelihood of in-water devices striking a coral reef would be considered rare and discountable.

Although the direct strike of coral reefs is rare and discountable, corals (including ESA-listed corals) broadcast spawn eggs and larvae into the water column where fertilization and early embryonic development occurs. The eggs, sperm, and larval stage of ESA-listed corals could remain in the water column for extended periods where they may be subjected to cavitation that are similar to natural processes. The effect from cavitation caused by in-water devices is discussed in Section 6.7.7.1 below.

6.7.7.1 Effects of Cavitation from Vessels and In-Water Devices on Juvenile Corals

Three ESA-listed species are known to occur within the immediate surroundings of Guam or the CNMI including *Acropora globiceps*, *Acropora retusa*, and *Seriatopora aculeata*. Although the direct strike of coral reefs with vessel hulls is rare and discountable, corals (including ESA-listed corals) broadcast spawn eggs and larvae into the water column where fertilization and early embryonic development occurs. In Section 6.5, we defined an individual coral as a colony and outlined the lifestages of coral that are pertinent to this assessement. Here, we address the potential effects to individuals from impacts to reproduction and recruitment from cavitation stressors.

6.7.7.1.1 Exposure of Juvenile Coral Life Stages to Cavitation

Three ESA-listed species are known to occur within the immediate surroundings of Guam or the CNMI including *Acropora globiceps*, *Acropora retusa*, and *Seriatopora aculeata*. Given the nature of ESA-listed coral spawning, it is reasonable to assume vessels and in-water devices will pass through water containing eggs, sperm, early embryonic stages, or planula larvae of the ESA-listed species occurring near Guam and the CNMI, where higher concentrations of vessel traffic and these life stages are likely to occur.

The eggs, sperm, and larval stage (Figure 15) of ESA-listed corals could remain in the water column for extended periods. Each individual polyp of an *Acropora* coral can produce 16 eggs and concentrations of sperm can be as high as 1 million per milliliter of seawater during spawning. Fertilized eggs develop into planula larvae within 5 days in *Acropora* species but these larvae can also remain in the water column over 200 days before settling. Although the reproductive effort and developmental timing of *Seriatopora* species are not as well known it is possible they are similar to *Acropora* species.

We assume that individuals in these life stages (eggs, sperm, early embryonic stages, or planula larvae) that occur offshore are less likely to come into contact with this stressor due to lower densities (greater volume of water), and a lower concentration of training and testing activities as compared to nearshore Guam and potentially the mouth of Apra Harbor.

6.7.7.1.2 Response of Corals to Cavitation

The eggs of *Acropora millepora*, a congeneric species to two of the ESA-listed species in the Action Area, are known to disintegrate into irregular groups or individual blastomeres when subjected to even very light shearing forces and turbulence (Heyward and Negri 2012). Under laboratory conditions these disintegrated cells commonly reorganized and continued development into eventual juveniles (Heyward and Negri 2012). Therefore, the disassociation of embryonic cells can be beneficial through the creation of more juveniles, although it is suspected others suffered direct mortality from being disassociated. In a manual for coral larvae rearing for reef rehabilitation, Guest et al. (2010), suggests rough handling of broadcast spawning coral embryos during early cell division stages (up to 36 hours post fertilization) will result in many embryo deaths or embryos being smaller than normal. Mead and Denny (1995) found turbulent water decreased successful fertilization of broadcast spawned eggs in the purple sea urchin, likely due to mechanical separation of eggs and sperm. The authors also found fertilized eggs exposed to high shear stresses of turbulent water showed abnormal development and low survival (Mead and Denny 1995). Shear stress from water turbulence has also been reported to cause increased mortality in fish eggs (Bunn et al. 2000; Eshenroder et al. 1994; Morgan et al. ; Sutherland and Ogle 1975).

Life stages subjected to cavitation from vessels and in-water devices could be deformed, die, or experience a decreased likelihood of fertilization. However, as described above, the reproductive biology of *Acropora globiceps*, and other coral species, results in prolific larval production and high natural mortality from a combination of factors including predation and dispersal to areas within the ocean without appropriate settlement habitat (e.g., deeper water, colder water, inappropriate substrate). Any anthropogenic mortality from the Navy's actions is likely to be infinitesimally small by comparison (L. Smith, personal communication, May 6, 2015) and biologically insignificant. Additionally, of the 19 threats to coral identified in the 2011 status review report of the 82 candidate coral species petitioned under the U.S. Endangered Species Act (Brainard et al. 2011a) and the top 9 threats to coral analyzed in the final rule (79 FR 53851), none include mortality of larvae by physical contact such as cavitation. While cavitation from vessels and in-water devices may result in the mortality of the developmental stages of *Acropora globiceps* (and other ESA-listed coral species), it likely would have an insignificant effect on the reproductive potential for an individual (i.e., colony) of the species or recruitment at the population level of this species. Since this level of effect is not expected to be signficant and detectable at the individual level (i.e., colony) we would not consider this effect to be a reduction in fitness of any colony of *Acropora globiceps* and thus we do not anticipate any population-level effects.

6.8 Stressors That Are Likely to Adversely Affect ESA-Listed Species

The following sections discuss stressors that are likely to adversely affect ESA-listed species. If a stressor is likely to adversely affect any of the ESA-listed species in the MITT Action Area, it

is discussed further in this Section. We address the specific species that are not likely to be adversely affected by the stressor in respective sections.

6.8.1 Effects of Collisions with Vessels

Navy vessels could strike ESA-listed animals during the course of training and testing activities. For example, within the SOCAL Range Complex, Navy vessels conducting training and testing have struck three whales over the last 10 years and in the Hawaii Range Complex, the Navy struck two whales over the last ten years. However, these are areas where the number of military vessels is generally much higher and training and testing activities occur more often than in the MITT Action Area. The Navy has been training and testing in the MITT Action Area for many years, and there has never been a documented case of a vessel striking an ESA-listed animal.

Vessels strikes could occur from surface operations or sub-surface operations (excluding bottom crawling, unmanned underwater vehicles). Vessels include ships, submarines and boats ranging from 16 ft (5 m) Rigid Hull Inflatable Boats (RHIB) to aircraft carriers (CVN) with lengths up to 1,092 ft (333 m). Navy ships greater than 60 ft (18 m) in length generally operate at 10 to 15 knots for fuel conservation when cruising. Submarines generally operate at 8 to 13 knots during surface transits and slower for certain tactical maneuvers, and greater speeds when submerged. Craft less than 60 ft (18 m) in length have more variable speeds, dependent on the mission. While these speeds are representative, some vessels operate outside of these speeds due to unique training and testing or safety requirements for a given event. Examples include increased speeds needed for flight operations, full speed runs to test engineering equipment, and time critical positioning needs. Examples of decreased speeds of less than 5 knots or completely stopped include launching small boats, certain tactical maneuvers, and target launch or retrievals.The number of participating vessels in the Action Area varies based on training and testing schedules. Most activities include either one or two vessels, with an average of one vessel per activity, and last from a few hours up to 2 weeks. Multiple ships, however, can be involved with major training events, although ships can often operate for extended periods beyond the horizon and out of visual sight from each other. A majority of vessel transit in the Action Area will occur in concentrated locations near docks and ports, particularly in and around Apra Harbor.

The Navy employs several actions to minimize to minimize collisions between surface vessels and ESA-listed animals that might occur in the Action Area. These measures include lookouts and watchstanders on the bridge of ships, requirements for course and speed adjustments to maintain safe distances from whales, and having any ship that observes whales to alert other ships in the area. Navy policy (Chief of Naval Operations Instruction 3100.6H) requires participating vessels to report all whale strikes. That information is collected by the Office of the Chief of Naval Operations Energy and Environmental Readiness Division and cumulatively provided to NMFS on an annual basis. In addition, the Navy and NMFS have standardized regional reporting protocols for communicating to NMFS stranding coordinators information on any ship strikes as soon as possible. These communication procedures will remain in place as part of this proposed action.

6.8.1.1 Cetaceans

Vessel strikes from commercial, recreational, and Navy vessels are known to affect large whales and have resulted in serious injury and occasional fatalities to cetaceans (Lammers et al. 2003) (Laggner 2009) (Calambokidis 2012) (Douglas et al. 2008) (Berman-Kowalewski et al. 2010). Reviews of the literature on ship strikes mainly involve collisions between commercial vessels and whales (e.g., Laist et al. (2001) Jensen and Silber (2004)). The ability of any ship to detect a marine mammal and avoid a collision depends on a variety of factors, including environmental conditions, ship design, size, speed, and manning, as well as the behavior of the animal. Records of collisions date back to the early 17th century, and the worldwide number of collisions appears to have increased steadily during recent decades (Laist et al. 2001; Ritter 2012) (IWC, 2008).

Vessel speed, size and mass are all important factors in determining potential impacts of a vessel strike to marine mammals. For large vessels, speed and angle of approach can influence the severity of a strike. Based on modeling, Silber et al. (2010) found that whales at the surface experienced impacts that increased in magnitude with the ship's increasing speed. Results of the study also indicated that potential impacts were not dependent on the whale's orientation to the path of the ship, but that vessel speed may be an important factor. At ship speeds of 15 knots or higher (7.7 m/second), there was a marked increase in intensity of centerline impacts to whales. Results also indicated that when the whale was below the surface (about one to two times the vessel draft), there was a pronounced propeller suction effect. This suction effect may draw the whale into the hull of the ship, increasing the probability of propeller strikes (Silber et al. 2010).

Key points in discussion of participating vessels in relationship to potential ship strike include:

- Many military ships have their bridges positioned closer to the bow, offering better visibility ahead of the ship (compared to a commercial merchant vessel).
- There are often aircraft associated with the training or testing activity, which can more readily detect cetaceans in the vicinity of a vessel or ahead of a vessel's present course before crew on the vessel would be able to detect them.
- Military ships are generally more maneuverable than commercial merchant vessels, and if cetaceans are spotted in the path of the ship, would be capable of changing course more quickly. Military ships operate at the slowest speed possible consistent with either transit needs or training or testing needs. While minimum speed is intended as a fuel conservation measure particular to a certain ship class, secondary benefits include better ability to spot and avoid objects in the water including marine mammals. In addition, a standard operating procedure for Navy vessels is to maneuver the vessel to maintain a distance of at least 500 yd. (457 m) from any observed whale and to avoid approaching whales head-on, as long as safety of navigation is not imperiled.
- The crew size on military vessels is generally larger than merchant ships, allowing for the possibility of stationing more trained Lookouts on the bridge. At all times when vessels are underway, trained Lookouts and bridge navigation teams are used to detect objects on the surface of the water ahead of the ship, including cetaceans. Additional Lookouts, beyond those already stationed on the bridge and on navigation teams, are positioned as Lookouts during some training events.
- Lookouts receive extensive training including Marine Species Awareness Training, which instructs Lookouts to recognize marine species detection cues (e.g., floating

vegetation or flocks of seabirds) as well as provides additional information to aid in the detection of cetaceans.

While it is possible for a Navy vessel to strike a cetacean during the course of training and testing activities in MITT Action Area, we do not believe this is reasonably certain to occur. As stated previously, the Navy has been training in the Action Area for years and no such incident has occurred. Additionally, the Navy employs minimization measures to reduce the likelihood for a surface vessel to strike a large whale. For these reasons, we consider the likelihood that a cetacean will be struck during Navy training and testing activities so low as to be discountable. Therefore, this stressor is not likely to adversely affect ESA-listed cetaceans and will not be considered further in this Opinion.

6.8.1.2 Sea turtles

The following sections discuss the effects of vessel strike on ESA-listed turtles.

6.8.1.2.1 Exposure of sea turtles to vessel strike

Any of the sea turtles species present in the Action Area can occur at or near the surface of the water, and therefore may be susceptible to vessel strike. There are no reported cases of a sea turtle being struck by a Navy vessel in the MITT Action Area. However, unlike when a vessel strikes a large whale, it is difficult to detect when a vessel strikes a turtle. This is largely due to the relatively small size of a sea turtle compared to the vessels used by the Navy in military readiness training and testing.

As described in Table 47, densities of leatherback and loggerhead sea turtles are very low in the MITT Action Area (i.e., < 0.00022 animals/km^2), particularly in the inshore environment near docks and ports where most of the vessel traffic is concentrated. Because of these low densities and the low amount of Navy vessel traffic that will occur in the MITT Action Area, we consider the likelihood for an individual of any of these species to be struck during Navy training and testing activities in the MITT Action Area to be so low as to be discountable.

Green and hawksbill sea turtles are more common in the Action Area, particularly in the nearshore environment (Table 47), and have a much higher likelihood of encountering moving Navy vessels. It is possible that green and hawksbill sea turtles will exhibit avoidance behavior in the event they encounter a Navy vessel in transit. If this occurs, the turtle would be expected to resume normal activities shortly after the initial avoidance response. This brief avoidance behavior of green and hawksbill sea turtles will not increase the likelihood of injury from significant disruption of breeding, feeding, or sheltering. Hazel et al. (2007) studied the behavioral responses of green turtles to vessels approaching at varying speeds. With the assumption that how quickly a turtle responds to an oncoming vessels is dependent on how soon the turtle can detect the oncoming vessel, they determined that the majority of turtles will likely not be able to avoid vessels traveling faster than 4 km/hr. While Navy vessels in nearshore areas, particularly around docks and ports are expected to travel at slower speeds than in offshore environments, some green and hawksbill turtles in these nearshore areas are expected to be susceptible to vessel strike because some vessels in these areas are likely to be traveling at speeds greater than 4km/hr.

Previous NMFS Biological Opinions have relied on sea turtle stranding network data to estimate mortality from vessel strike (e.g., Hawaii Troll and Handline BiOp; Hawaii-Southern California Training and Testing). Navy vessel movement is expected to be most concentrated in and around Apra Harbor, where major docking facilities exist. Outside of Apra Harbor, including deep-water, offshore areas, vessel traffic is assumed to be much less dense. Therefore, we expect Apra Harbor to be the only area in which sea turtle strikes are reasonably expected to occur. Although little information exists to quantify this impact, vessel collision has been implicated as the cause of three green turtle strandings in Apra Harbor between November 2002 and April 2008 (DAWR unpublished data). Corraborating that Apra Harbor is the most likely location for vessel strike to occur, stranding data around Saipan and Tinian found evidence of vessel strike in only two of 70 green sea turtle, and zero of three hawksbill sea turtle strandings between from 2005 to 2015 (sea turtle stranding network, unpublished data). Military activities around Saipan and Tinian are not associated with heavy vessel traffic. Though available information does not allow us to estimate the percentage of vessel struck turtles that are observed stranded in Apra Harbor, we expect this observed stranding rate to be fairly high due to the human population along the Harbor and that it is relatively enclosed. Therefore, using stranding rates from Hawaii as proxy (i.e., 20 to 40 percent of struck turtles are likely to strand), we assume 40 percent of vessel struck sea turtles will strand (NMFS 2008c). From the 3 observed strandings in Apra Harbor with evidence of vessel strike between November 2002 and April 2008, we estimate a total of 8 turtles were struck by vessels during this time period (3 turtles / 0.4 = 7.5 turtles). This comes to an annual strike rate of 1.36 green sea turtles per year (7.5 turtles / 5.5 years = 1.36 turtles per year).

Navy vessels account for a large percentage of the vessel traffic in Apra Harbor, but substantial traffic also occurs from recreational and commercial vessels. The of Port of Guam had 635 non-Navy vessel calls in 2013, while the Navy reports 389 Navy vessel calls in 2014 (1,024 total vessel calls). Therefore, Navy vessels account for approximately 38 percent of the large vessel traffic in and out of the Port of Guam on an annual basis. Since we do not have data to indicate how many smaller, recreational boats transit through Apra Harbor, we conservatively estimate that Navy vessel traffic accounts for 38 percent of the vessel movement within Apra Harbor. Therefore, we expect that on average, the Navy will strike up to 1 green turtle per year (1.36 turtles per year x 0.38 = 0.52; rounded up to 1 turtle).

After further analysis, given the lack of stranding data associated with vessel strikes in the Action Area, and the lower abundance and sighting data of hawksbill sea turtles in Apra Harbor, it is not reasonable to expect Navy vessels will strike this species. Therefore, the likelihood of Navy vessels striking a hawksbill sea turtle is so low as to be discountable.

6.8.1.2.2 Response of sea turtles to vessel strike

Ship strikes are known to injure and kill sea turtles (Work et al. 2010a). Stranding networks that keep track of sea turtles that wash up dead or injured have consistently recorded vessel propeller strikes as a cause or possible cause of death (Chaloupka et al. 2008b). We conclude that collisions with vessels would likely result in blunt trauma, lacerations, and mortality.

6.8.1.3 Scalloped Hammerhead Shark – Indo-West Pacific DPS

Scalloped hammerhead sharks in the Action Area may encounter moving Navy vessels. However, it is expected that this highly mobile and fast swimming species will exhibit evasive

behavior in the event they encounter a Navy vessel at close range and will be able to avoid being struck. Further, it is expected that sharks will return to normal behavior shortly after avoiding the oncoming vessel as with other natural evasive responses where the perceived threat has passed. Any temporary avoidance behavior will not increase the likelihood of injury from significant disruption of breeding, feeding, or sheltering and is not expected to rise to the level of take. For these reasons, scalloped hammerhead sharks are not likely to be adversely affected by vessel strike stressors since brief behavioral avoidance is considered insignificant.

6.8.1.4 Corals

Though unlikely (with the exception of Amphibious Assault and Amphibious Raid Operations, as described below), Navy vessels may contact the benthos, including coral reefs, during training and testing activities. If a Navy vessel struck an ESA-listed coral colony, this could result in colony fragmentation, injury, or mortality. However, we do not believe vessel strike of coral colonies is reasonably certain to occur. In nearshore habitats, where a large percentage of the vessel traffic is concentrated, most Navy vessel movements are confined to established channels, ports, or transit lanes. These areas are frequently used by vessels (Navy and non-Navy), and have water deep enough to where vessels do not contact coral reef or other substrate types. For movement in nearshore habitats not in established channels or transit lanes, vessels are not expected to contact coral reef habitats because they are equipped with appropriate navigational equipment and vessel operators actively avoid running aground (this excludes Amphibious Assault and Amphibious Raid operations). Additionally, Navy vessels are not expected to strike coral reefs in offshore habitats because waters are deep enough to where vessels will not contact coral reef or other substrate types. For these reasons, we consider the likelihood of an ESA-listed coral being struck by a Navy vessel during training and testing activities (excluding Amphibious Assault and Amphibious Raid Operations, which is addressed below) to be so low as to be discountable.

Navy vessels could contact benthic habitat in areas adjacent to corals in the surf zone during Amphibious Assault and Amphibious Raid operations. However, due to the minimization measures described below, vessels are expected to avoid direct contact with coral colonies. Amphibious Assault and Amphibious Raid training activities would be conducted in the nearshore area, including the surf zone, up to the high tide line. Prior to conducting any amphibious over-the-beach training activity with larger amphibious vehicles such as Landing Craft Air Cushions (LCACs) or Amphibious Assault Vehicles (AAVs), surveys would be conducted to identify and designate boat lanes and beach landing areas that are clear of coral, hard bottom substrate, and obstructions. Based on the surveys, if the beach landing area and boat lane is clear, the activity could be conducted, and crews would follow procedures to avoid obstructions to navigation, including coral reefs. However, if the survey indicates there is any potential for impacts on corals or hard bottom substrate, the Navy will coordinate with applicable resource agencies before conducting the activity. Further, LCAC and AAV landing and departure activities would be scheduled at high tide, decreasing the likelihood that a vessel would contact coral colonies. If necessary to traverse over areas with coral or other hard-bottom substrate, LCACs and AAVs would hover over, but avoid direct contact with such habitats. Surveys would not be necessary for beach landings with small boats, such as RHIBs. We do not expect small boats to contact coral reefs during this activity because it would be a navigational and safety

hazard for vessels of this size to strike exposed or near-surface substrate. For reasons described above, we consider the likelihood of an ESA-listed coral being struck by a Navy vessel during Amphibious Assault and Amphibious Raid operations to be so low as to be discountable.

Precision anchoring will occur in Apra Harbor and other existing anchorages in the Mariana Islands. Except in existing anchorages and near-shore training areas around Guam and within Apra Harbor, Navy vessels will not anchor within the anchor swing diameter of surveyed shallow coral reefs, live hardbottom, articificial reefs, or shipwrecks. Recent studies have identified evidence of anchor and/or anchor chain damage to coral in Apra Harbor, including the formation of a rubble field on the southern side of the floating dry dock. Movement of mooring chains on the southern side of the floating dry dock has produced a significant rubble field, although mooring chains on the northern (outer) side of the floating dry dock do not appear to have caused similar damage (DoN 2010b). Available data suggests ESA-listed corals do not occur at existing Navy anchorages in Apra Harbor or other locations. Therefore, we consider the likelihood of Navy anchorage impacting ESA-listed coral species to be so low as to be discountable.

ESA-listed corals are not expected to be affected by vessel strike; therefore, no response analysis is necessary.

6.8.2 Overview of Effects of Acoustic Stressors

The U.S. Navy grouped approximately 300 individual sources of underwater acoustic sound or explosive energy, into a series of source classifications, or source bins. There are two primary types of source classes: "Impulsive" and "Non-impulsive" acoustic. A description of each source classification analyzed for marine mammals is provided in Table 48 and Table 49 below.

Table 48. Training and Testing Non-Impulsive Acoustic Sources Analyzed for Marine Mammals

Source Class Category	Source Class	Description
Low-Frequency (LF): Sources that produce low-frequency (less than 1 kHz) signals	LF4	Low-frequency sources equal to 180 dB and up to 200 dB
	LF5	Low-frequency sources less than 180 dB
	LF6	Low-frequency sonar currently in development (e.g., ASW sonar associated with the LCS)
Mid-Frequency (MF): Tactical and non-tactical sources that produce mid-frequency (1–10 kHz) signals	MF1	Hull-mounted surface ship sonar (e.g., AN/SQS-53C and AN/SQS-60)
	MF2	Hull-mounted surface ship sonar (e.g., AN/SQS-56)
	MF3	Hull-mounted submarine sonar (e.g., AN/BQQ-10)
	MF4	Helicopter-deployed dipping sonar (e.g., AN/AQS-22 and AN/AQS-13)
	MF5	Active acoustic sonobuoys (e.g., DICASS)
	MF6	Active underwater sound signal devices (e.g., MK-84)
	MF8	Active sources (greater than 200 dB)

		not otherwise binned
	MF9	Active sources (equal to 180 dB and up to 200 dB)
	MF20	Active sources (greater than 160 dB, but less than 180 dB) not otherwise binned
	MF11	Hull-mounted surface ship sonars with an active duty cycle greater than 80%
	MF12	High duty cycle – variable depth sonar
High-Frequency (HF) and Very High-Frequency (VHF): Tactical and non-tactical sources that produce high-frequency (greater than 10 kHz but less than 200 kHz) signals	HF1	Hull-mounted submarine sonar (e.g., AN/BQQ-10)
	HF4	Mine detection, classification, and neutralization sonar (e.g., AN/SQS-20)
	HF5	Active sources (greater than 200 dB)
	HF6	Active sources (equal to 180 dB and up to 200 dB)
Anti-Submarine Warfare (ASW): Tactical sources such as active sonobuoys and acoustic countermeasures systems used during the conduct of anti-submarine warfare testing activities	ASW1	Mid-frequency DWADS
	ASW2	Mid-frequency MAC sonobuoy (e.g., AN/SSQ-125)
	ASW3	Mid-frequency towed active acoustic countermeasure systems (e.g., AN/SLQ-25)
Torpedoes (TORP): Source classes associated with the active acoustic signals produced by torpedoes	TORP1	Lightweight torpedo (e.g., MK-46, MK-54, or Anti-Torpedo Torpedo)
	TORP2	Heavyweight torpedo (e.g., MK-48)
Acoustic Modems (M): Systems used to transmit data acoustically through water	M3	Mid-frequency acoustic modems (greater than 190 dB)
Swimmer Detection Sonar (SD): Systems used to detect divers and submerged swimmers	SD1	High-frequency sources with short pulse lengths, used for the detection of swimmers and other objects for the purpose of port security.

Notes: dB = decibels, DICASS = Directional Command Activated Sonobuoy System, DWADS = Deep Water Active Distributed System, kHz = kilohertz, LCS = Littoral Combat Ship, MAC = Multi-static Active Coherent

Table 49. Training and Testing Explosive Sources Analyzed for Marine Mammals

Source Class	Representative Munitions	Net Explosive Weight (lb.)[1]
E1	Medium-caliber projectiles	0.1–0.25
E2	Medium-caliber projectiles	0.25–0.5
E3	Large-caliber projectiles	> 0.5–2.5
E4	Improved Extended Echo Ranging Sonobuoy	> 2.5–5.0
E5	5-inch projectiles	> 5–10
E6	15 lb. shaped charge	> 10–20
E8	250 lb. bomb	> 60–100
E9	500 lb. bomb	> 100–250

E10	1,000 lb. bomb	> 250–500
E11	650 lb. mine	> 500–650
E12	2,000 lb. bomb	> 650–1,000

[1]**Net Explosive Weight refers to the amount of explosives; the actual weight of a munition may be larger due to other components**

Activities and acoustic source classes modeled for sea turtles are provide in the Table 50 below:

Table 50. Activities and Active Acoustic Sources Modeled and Quantitatively Analyzed by the U.S. Navy for Acoustic Impacts on Sea Turtles (Reference FEIS/OEIS V2, June 2014)

Activity	Acoustic Source Class
Training Activity	
Joint Expeditionary Exercise	ASW2, ASW3, MF1, MF12, MF2, MF3, MF4, MF5
Joint Multi-Strike Group Exercise	ASW2, ASW3, ASW4, MF1, MF11, MF12, MF2, MF3, MF4, MF5
Marine Air Ground Task Force Exercise (Amphibious)	ASW3, MF1, MF12, MF2, MF3, MF4
TRACKEX/TORPEX – MPA Advanced Extended Echo Ranging Sonobuoys	ASW2
TRACKEX/TORPEX – Surface	ASW3, MF1, MF11, MF12, MF2, TORP1
Testing Activity	
Anti-Submarine Warfare Tracking Test – Maritime Patrol Aircraft	ASW2, MF5, MF6, TORP1
ASW Mission Package Testing	ASW1, ASW3, LF6, MF12, MF4, MF5
At-Sea Sonar Testing	ASW1, LF5, M3, MF1, MF10, MF11, MF3, MF9
Pierside Integrated Swimmer Defense	LF4, MF8, SD1

In order to better organize and facilitate the analysis of about 300 sources of underwater non-impulsive sound or impulsive energy, the Navy developed a series of source classifications, or source bins. This method of analysis provides the following benefits:

- Allows for new sources to be covered under existing authorizations, as long as those sources fall within the parameters of a "bin;"
- Simplifies the data collection and reporting requirements anticipated under the MMPA;
- Ensures a conservative approach to all impact analysis because all sources in a single bin are modeled as the loudest source (e.g., lowest frequency, highest source level, longest duty cycle, or largest net explosive weight within that bin);
- Allows analysis to be conducted more efficiently, without compromising the results; and
- Provides a framework to support the reallocation of source usage (hours/explosives) between different source bins, as long as the total number and severity of marine mammal takes remain within the overall analyzed and authorized limits. This flexibility

is required to support evolving Navy training and testing requirements, which are linked to real world events.

Non-impulsive sources are grouped into bins based on the frequency, source level when warranted, and how the source would be used. Impulsive bins are based on the net explosive weight of the munitions or explosive devices. The following factors further describe how non-impulsive sources are divided:

Frequency of the non-impulsive source:

- Low-frequency sources operate below 1 kilohertz (kHz)
- Mid-frequency sources operate at or above 1 kHz, up to and including 10 kHz
- High-frequency sources operate above 10 kHz, up to and including 100 kHz
- Very high-frequency sources operate above 100 kHz, but below 200 kHz

Source level of the non-impulsive source:

- Greater than 160 decibels (dB), but less than 180 dB
- Equal to 180 dB and up to 200 dB
- Greater than 200 dB

How a sensor is used determines how the sensor's acoustic emissions are analyzed. Factors to consider include pulse length (time source is on); beam pattern (whether sound is emitted as a narrow, focused beam, or, as with most explosives, in all directions); and duty cycle (how often a transmission occurs in a given time period during an event).

There are also non-impulsive sources with characteristics that are not anticipated to result in takes of marine mammals under the MMPA or ESA. These sources have low source levels, narrow beam widths, downward directed transmission, short pulse lengths, frequencies beyond known hearing ranges of marine mammals, or some combination of these factors. These sources were not modeled by the Navy, but are qualitatively analyzed in the MITT FEIS/OEIS, May 2015.

Understanding the number of munitions detonating in water is critical to assessing potential impacts from acoustic stressors, potential strike and fragments resulting from exploded munitions. Table 51 below provides the number and source of these munitions.

Table 51. Proposed Annual Number of Impulsive Source Detonations During Training and Testing in the MITT Action Area

Explosive Class	Net Explosive Weight (NEW)	Annual In-Water Detonations
E1	(0.1 lb. – 0.25 lb.)	10,140
E2	(0.26 lb. – 0.5 lb.)	106
E3	(>0.5 lb. – 2.5 lb.)	932
E4	(>2.5 lb. – 5 lb.)	420
E5	(>5 lb. – 10 lb.)	684
E6	(>10 lb. – 20 lb.)	76
E8	(>60 lb. – 100 lb.)	16
E9	(>100 lb. – 250 lb.)	4
E10	(>250 lb. – 500 lb.)	12
E11	(>500 lb. – 650 lb.)	6
E12	(>650 lb. – 2,000 lb.)	184

Understanding the frequency and duration of active sonar sources is imperative in our risk analysis for stressors resulting from non-impulsive sound sources. Table 52 below provide the annual hours of these sources in the MITT Action Area.

Table 52. Annual hours and items of non-impulsive sources used during training and testing within the MITT Action Area

Source Class Category	Source Class	Average Annual Use
Low-Frequency (LF) Sources that produce signals less than 1 kilohertz (kHz)	LF4	123 hours
	LF5	11 hours
	LF6	40 hours
Mid-Frequency (MF) Active sources from 1 to 10 kHz	MF1	1,872 hours
	MF2	625 hours
	MF3	192 hours
	MF4	214 hours
	MF5	2,588 hours
	MF6	33 hours
	MF8	123 hours
	MF9	47 hours
	MF10	231 hours
	MF11	324 hours
	MF12	656 hours

Source Class Category	Source Class	Average Annual Use
High-Frequency (HF) and Very High-Frequency (VHF) Tactical and non-tactical sources that produce signals greater than 10kHz but less than 200kHz	HF1	113 hours
	HF4	1,060 hours
	HF5	336 hours
	HF6	1,173 hours
Anti-Submarine Warfare (ASW) Tactical sources used during anti-submarine warfare training and testing activities	ASW1	144 hours
	ASW2	660 hours
	ASW3	3,935 hours
	ASW4	32 hours
Torpedoes (TORP) Source classes associated with active acoustic signals produced by torpedoes	TORP1	115 hours
	TORP2	62 hours
Acoustic Modems (M) Transmit data acoustically through the water	M3	112 hours
Swimmer Detection Sonar (SD) Used to detect divers and submerged swimmers	SD1	2,341 hours
Airgun (AG)1	AG	308 hours

Notes: dB = decibels, DICASS = Directional Command Activated Sonobuoy System, DWADS = Deep Water Active Distributed System, kHz = kilohertz, LCS = Littoral Combat Ship, MAC = Multi-static Active Coherent

6.8.3 Effects of Non-Impulsive Acoustic Stressors - Cetaceans

For this consultation, we considered exposure estimates from the Navy Acoustic Effects Model at two output points for marine mammals. First, the total number of ESA-listed species (animats) that would be exposed to acoustic sources greater than 120dB prior to the application of a dose-response curve or criteria. We term these the "unprocessed" estimates. This estimate is the number of times individual animats or animals are likely to be exposed to the acoustic environment that is a result of training exercises and testing activities, regardless of whether they are "taken" as a result of that exposure. In most cases, the number of animals "taken" by an action would be a subset of the number of animals that are exposed to the action because (1) in some circumstances, animals might not respond to an exposure and (2) some responses may be negative for an individual animal without constituting a form of "take" (for example, some physiological stress responses only have fitness consequences when they are sustained and would only constitute a "take" as a result of cumulative exposure).

The second set (Table 55) of predicted exposures ("processed") of listed species were generated and processed using dose-response curves and criteria for temporary and permanent threshold shift developed by the Navy and NMFS' Permits Division for the purpose of identifying

harassment pursuant to the MMPA. Neither sets of exposure estimates, the unprocessed or processed, consider standard mitigation actions that NMFS' Permits Division would require under the MMPA rule to avoid marine mammals or that the Navy proposes for marine mammals, nor did the estimates consider any avoidance responses that might be taken by individual animals once they sense the presence of Navy vessels or aircraft.

Our estimation of take is derived from the processed exposure estimates on an annual basis, cumulatively over the five-year period, and cumulatively for the reasonably foreseeable future to derive a final estimate of anticipate levels of take by training activity and species.

6.8.3.1 Exposures to Non-impulsive Acoustic Stressors During Training

The following sections discuss the exposure of ESA-listed species to non-impulsive acoustic stressors.

6.8.3.1.1 Unprocessed Exposures to Non-Impulsive Acoustic Stressors During Training

Navy model output estimates of whales that will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities above received levels of 120 dB throughout the year are summarized in Table 53 and discussed below. Exposures at levels above 120 dB may result in behavioral or physiological responses (see Section 6.2).

Table 53. Model-Predicted Exposures of Cetaceans to Non-Impulsive Sound During Training Activities

Species	Number of Model-Predicted Exposures >120 dB Per Year
blue whale	195
fin whale	208
humpback whale	10,862
sei whale	3,378
sperm whale	14,813

Blue whale. The model output estimates that blue whales will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities throughout the year. The NAEMO provided an unprocessed estimate of 195 blue whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Thirty-seven (37) percent of the estimated 195 exposures to blue whales during training activities will result from TRACKEX/TORPEX – Surface exercises while 13 percent will result from Joint Expeditionary Exercises and 10 percent result from Joint Multi-Strike Group Exercises.

Fin whale. The model output estimates that fin whales will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities throughout the year. The NAEMO provided an unprocessed estimate of 208 fin whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Forty (40) percent of the estimated 208 exposures to fin whales during training activities will result from TRACKEX/TORPEX – Surface exercises while 12 percent will result from Joint Expeditionary Exercises and 12 percent result from Joint Multi-Strike Group Exercises.

Humpback whale. The model output estimates that humpback whales will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities throughout the year. The NAEMO provided an unprocessed estimate of 10,862 blue whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Forty-nine (49) percent of the estimated 10,862 exposures to humpback whales during training activities will result from TRACKEX/TORPEX – Surface exercises while 10 percent will result from Joint Expeditionary Exercises and 12 percent result from Joint Multi-Strike Group Exercises.

Sei whale. The model output estimates that sei whales will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities throughout the year. The NAEMO provided an unprocessed estimate of 3,378 sei whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Forty-seven (47) percent of the estimated 3,378 exposures to sei whales during training activities will result from TRACKEX/TORPEX – Surface exercises while 10 percent will result from Joint Expeditionary Exercises and 13 percent result from Joint Multi-Strike Group Exercises.

Sperm whale. The model output estimates that blue whales will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities throughout the year. The NAEMO provided an unprocessed estimate of 14,813 sperm whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Forty-nine (49) percent of the estimated 14,813 exposures to sperm whales during training activities will result from TRACKEX/TORPEX – Surface exercises while 11 percent will result from Joint Expeditionary Exercises and 13 percent result from Joint Multi-Strike Group Exercises.

6.8.3.1.2 Unprocessed Exposures to Non-Implusive Acoustic Stressors During Testing

Navy model output estimates of whales that will be exposed to sonar and other non-impulsive acoustic stressors associated with testing activities throughout the year are summarized in Table 54 and discussed below.

Table 54. Model-Predicted Exposures of Cetaceans to Non-Impulsive Sound During Testing Actvities

Species	Number of Model-Predicted Exposures >120 dB Per Year
blue whale	102
fin whale	115
humpback whale	4,179
sei whale	1,330
sperm whale	5,941

Blue whale. The model output estimates that blue whales will be exposed to sonar and other non-impulsive acoustic stressors associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 102 blue whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Forty-seven (47) percent of the estimated 102 exposures to blue whales during testing activities will result from Anti-submarine Warfare Tracking Test – Marine Patrol Aircraft while 33 percent will result from ASW Mission Package Testing and 15 percent result from At-Sea Sonar Testing.

Fin whale. The model output estimates that fin whales will be exposed to sonar and other non-impulsive acoustic stressors associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 115 fin whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Fifty (50) percent of the estimated 115 exposures to fin whales during training activities will result from Anti-submarine Warfare Tracking Test – Marine Patrol Aircraft while 32 percent will result from ASW Mission Package Testing and 13 percent result from At-Sea Sonar Testing.

Humpback whale. The model output estimates that humpback whales will be exposed to sonar and other non-impulsive acoustic stressors associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 4,179 humpback whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Thirty-seven (37) percent of the estimated 4,179 exposures to humpback whales during training activities will result from Anti-submarine Warfare Tracking Test – Marine Patrol Aircraft while 46 percent will result from ASW Mission Package Testing and 14 percent result from At-Sea Sonar Testing.

Sei whale. The model output estimates that sei whales will be exposed to sonar and other non-impulsive acoustic stressors associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 1,330 sei whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Thirty-seven (37) percent of the estimated 1,330 exposures to sei whales during training activities will result result from Anti-submarine Warfare Tracking Test – Marine Patrol Aircraft while 46 percent will result from ASW Mission Package Testing and 13 percent result from At-Sea Sonar Testing.

Sperm whale. The model output estimates that sperm whales will be exposed to sonar and other non-impulsive acoustic stressors associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 5,941 sperm whale exposure events annually to non-impulsive sounds associated with annual training at levels above 120 dB SPL. Thirty-two (32) percent of the estimated 5,941 exposures to sperm whales during training activities will result result from Anti-submarine Warfare Tracking Test – Marine Patrol Aircraft while 50 percent will result from ASW Mission Package Testing and 14 percent result from At-Sea Sonar Testing.

6.8.3.1.3 Processed Exposures to Non-Impulsive Acoustic Stressors During Training and Testing

Humpback whale, blue whale, fin whale, and sei whale are all mysticetes. Research and observations show that if mysticetes are exposed to sonar or other active acoustic sources they may react in a number of ways depending on the characteristics of the sound source, their experience with the sound source, and whether they are migrating or on seasonal grounds (i.e., breeding or feeding grounds). Reactions may include alerting, breaking off feeding dives and surfacing, diving or swimming away, or no response at all (Southall et al. 2007b) (Southall et al. 2012) (Goldbogen et al. 2013; Melcon et al. 2012). Additionally, migrating mysticetes (such as humpback whales moving through the Action Area) may divert around sound sources that are located within their path or may ignore a sound source depending on the context of the exposure.

Animals that experience TTS may have reduced ability to detect relevant sounds such as predators, prey, or social vocalizations until their hearing recovers. Recovery from a threshold shift (i.e., TTS; temporary partial hearing loss) can take a few minutes to a few days depending on the severity of the initial shift. Threshold shifts do not necessarily affect all hearing frequencies equally, so some threshold shifts may not interfere with an animal's ability to hear biologically relevant sounds. For exposures resulting in TTS, long-term consequences for individuals or populations would not be expected.

Predicted effects (processed values) from sonar and other active acoustic sources on ESA-listed marine mammals are shown in Table 55. Only behavioral responses (non-TTS effects) and TTS effects are anticipated. Based on the exposure levels modeled, no PTS level detections are expected.

Table 55. Predicted Effects (processed values) on Endangered Species Act-Listed Marine Mammals from Annual Training and Testing Use of Sonar and Other Active Acoustic Sources

Species	Non-TTS (Behavioral)	TTS	PTS
Mysticetes			
Blue whale	3	25	0
Fin whale	4	24	0
Humpback whale	181	679	0
Sei whale	61	258	0
Odontocetes			
Sperm whale	452	54	0

6.8.3.2 Response of ESA-Listed Species to Non-Impulsive Acoustic Stressors

The following sections discuss the response of ESA-listed species to non-impulsive acoustic stressors.

6.8.3.2.1 Blue Whale

Temporary Threshold Shift (TTS) - As mentioned previously, TTS can last from a few minutes to days, be of varying degree, and occur across various frequency bandwidths, all of which determine the severity of the impacts on the affected individual, which can range from minor to more severe. The TTS sustained by an animal is primarily classified by three characteristics:

1. Frequency—Available data (of midfrequency hearing specialists exposed to mid- or high-frequency sounds; (Southall et al. 2007b)) suggest that most TTS occurs in the frequency range of the source up to one octave higher than the source (with the maximum TTS at ½ octave above). The more powerful mid-frequency sources used have center frequencies between 3.5 kHz and 8 kHz and the other unidentified mid-frequency sources are, by definition, less than 10 kHz, which suggests that TTS induced by any of these mid frequency sources would be in a frequency band somewhere between approximately 2 and 20 kHz. As discussed above, blue whales are low-frequency hearing specialists, producing low-frequency vocalizations that include moans in the range from 12.5 Hz to 400 Hz, with dominant frequencies from 16 Hz to 25 Hz. Therefore, even though recent studies (discussed below) indicate that blue whales hear and respond to mid-frequency sounds, it is unlikely that TTS caused by mid-frequency active sonar transmissions would

interfere with an animal's ability to hear vocalizations or most other biologically important sounds. There are fewer hours of high frequency source use and the sounds would attenuate more quickly, plus they have lower source levels, but if an animal were to incur TTS from these sources, it would cover a higher frequency range (sources are between 20 kHz and 100 kHz, which means that TTS could range up to 200 kHz; however, high frequency systems are typically used less frequently and for shorter time periods than surface ship and aircraft mid-frequency systems, so TTS from these sources is even less likely).

2. Degree of the shift (i.e., how many dB is the sensitivity of the hearing reduced by)—Generally, both the degree of TTS and the duration of TTS will be greater if the marine mammal is exposed to a higher level of energy (which would occur when the peak dB level is higher or the duration is longer). The threshold for the onset of TTS was discussed previously in this document. An animal would have to approach closer to the source or remain in the vicinity of the sound source appreciably longer to increase the received SEL, which would be difficult considering the lookouts, the sightability of blue whales and other listed mysticetes, and the nominal speed of an active sonar vessel (10 to 15 knots). In the TTS studies, some using exposures of almost an hour in duration or up to 217 SEL, most of the TTS induced was 15 dB or less, though Finneran et al. (2007) induced 43 dB of TTS with a 64-second exposure to a 20 kHz source. However, mid-frequency active sonar emits a nominal ping every 50 seconds, and incurring those levels of TTS is highly unlikely.

3. Duration of TTS (recovery time)—In the TTS laboratory studies, some using exposures of almost an hour in duration or up to 217 SEL, almost all individuals recovered within 1 day (or less, often in minutes), though in one study (Finneran et al. 2007), recovery took 4 days. Based on the range of degree and duration of TTS reportedly induced by exposures to non-pulse sounds of energy higher than that to which freeswimming marine mammals in the field are likely to be exposed during mid-frequency/high-frequency active sonar training exercises in the Action Area, it is unlikely that blue whales or other listed cetaceans would ever sustain a TTS from MFAS that alters their sensitivity by more than 20 dB for more than a few days (and any incident of TTS would likely be far less severe due to the short duration of the majority of the exercises and the speed of a typical vessel). Also, because of the short distance within which animals would need to approach the sound source, it is unlikely that animals would be exposed to the levels necessary to induce TTS in subsequent time periods such that their recovery is impeded.

In addition, the mitigation zones prescribed in the final MMPA rule encompass the ranges to PTS for the most sensitive marine mammal functional hearing group, which is usually the high-frequency cetacean hearing group. Therefore, the mitigation zones are even more protective for blue whales and other low-frquency cetaceans, and likely cover a larger portion of the potential range to onset of TTS. Accordingly, the prescribed mitigation and the sightability of blue whales and other mysticetes (due to their large size) reduce the potential for a significant TTS or behavioral reaction threshold shift to occur.

Therefore, for blue whales and other listed mysticetes analyzed in this Opinion, even though the modeled TTS estimates may change from year to year over baseline conditions, NMFS does not anticipate TTS of a long duration or severe degree to occur as a result of exposure to mid- or high-frequency active sonar utilized in the MITT Action Area.

The classification of modeled effects from acoustic stressors, such as TTS, are performed in a manner as to conservatively overestimate the impacts of those effects. Acoustic stressors are binned and all stressors within each bin are modeled as the loudest source, overestimating impacts within each bin. Therefore, the temporary duration of many TTS exposures may be on the shorter end of the range and last only a few minutes. Even longer duration TTS are expected to typically last hours. Given the brief amount of time blue whales are expected to experience TTS, it is unlikely to significantly impair their ability to communicate, forage, or breed and will not have fitness level consequences at the individual or population level. Results from 2 years (2009 and 2010) of intensive monitoring by independent scientists and Navy observers in the Southern California (SOCAL) and Hawaii Range Complexes have recorded an estimated 161,894 marine mammals with no evidence of distress or unusual behavior observed during Navy activities, supporting that TTS is unlikely to significantly impair the ability of blue whales to communicate, forage, or breed and will not have fitness level consequences at the individual or population level.

Behavioral Responses - As discussed, the Navy uses the behavioral response function to quantify the number of behavioral responses that would qualify as Level B behavioral harassment under the MMPA. As the statutory definition is currently applied, a wide range of behavioral reactions may qualify as Level B harassment under the MMPA, including but not limited to avoidance of the sound source, temporary changes in vocalizations or dive patterns, temporary avoidance of an area, or temporary disruption of feeding, migrating, or reproductive behaviors. The estimates calculated using the behavioral response function do not differentiate between the different types of potential reactions. Nor do the estimates provide information regarding the potential fitness or other biological consequences of the reactions on the affected individuals. We therefore consider the available scientific evidence to determine the likely nature of the modeled blue whale behavioral responses and the potential fitness consequences for affected individuals.

While we recognize that animal hearing evolved separately from animal vocalizations and, as a result, it may be inappropriate to make inferences about an animal's hearing sensitivity from their vocalizations, we have no data on blue whale hearing so we assume that blue whale vocalizations are partially representative of their hearing sensitivities. Blue whales are not likely to respond to high-frequency sound sources associated with the proposed training exercises and testing activities because of their hearing sensitivities. Despite previous assumptions based on vocalizations and anatomy that blue whales predominantly hear low-frequency sounds below 400 Hz (Croll et al. 2001b; Oleson et al. 2007b; Stafford and Moore 2005a), recent research has indicated blue whales not only hear mid-frequency active sonar transmissions, in some casesthey respond to those transmissions (Goldbogen et al. 2013; Melcon et al. 2012; Southall et al. 2011a).

As summarized in Section 6.2.10 and Section 6.2.10.2, blue whales may hear some sounds in the mid-frequency range and exhibit behavioral responses to sounds in this range depending on

received level and context (Goldbogen et al. 2013; Melcon et al. 2012). However, both Goldbogen et al. (2013) and Melcon et al. (2012) indicated that behavioral responses to simulated or operational MFA sonar were temporary, with whales resuming normal behavior quickly after the cessation of sound exposure. Further, responses were discernible for whales in certain behavioral states (i.e., deep feeding), but not in others (i.e., surface feeding). As stated in Goldbogen et al. (2013) when summarizing the response of blue whales to simulated MFA sonar, "We emphasize that elicitation of the response is complex, dependent on a suite of contextual (e.g., behavioral state) and sound exposure factors (e.g., maximum received level), and typically involves temporary avoidance responses that appear to abate quickly after sound exposure."

Melcon et al. (2012) reported that blue whales exposed to mid-frequency sonar in the Southern California Bight were less likely to produce low frequency calls (D calls) usually associated with feeding behavior. However, they they were unable to determine if suppression of D calls reflected a change in their feeding performance or abandonment of foraging behavior and indicated that implications of the documented responses are unknown. Goldbogen et al. (2013) speculated that if the documented temporary behavioral responses interrupted feeding behavior, this could have impacts on individual fitness and eventually, population health. However, for this to be true, we would have to assume that an individual whale could not compensate for this lost feeding opportunity by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no indication this is the case, particularly since unconsumed prey would likely still be available in the environment in most cases following the cessation of acoustic exposure.

Moreover, there are important differences between the acoustic sources used in the authors' Controlled Exposure Experiments. As discussed previously, perhaps the most significant reponse documented in the study occurred during a controlled exposure experiments involving pseudo-random noise rather than simulated sonar, which corresponded with a blue whale terminating a foraging bout. The more significant reaction to PRN may be indicative of habituation to mid-frequency sonar signals; the authors noted that the responses they documented were in a geographical region with a high level of naval activity and where mid-frequency sonar use is common.In addition, during the controlled exposure experiments, sound sources were deployed from a stationary source vessel positioned approximately 1,000 m from the focal animals, with one transmission onset every 25 seconds (Southall et al. 2012). In contrast, most Navy sonar systems are deployed from highly mobile vessels or in-water devices which do not directly target marine mammals. Further, the typical duty cycle with most tactical anit-submarine warefare is lower than used in the controlled exposure experiments described above, transmitting about once per minute minute with most active sonar pulses lasting no more than a few seconds (Navy 2013). Moreover, a typical Navy vessel with hull mounted MFA sonar would travel over 0.3 kilometers between pings (based on a speed of 10 knots/hr and transmission rate of 1 ping/min). Based on this distance traveled and potential avoidance behavior of acoustically exposed animals, we expect repeat acoustic exposures capable of eliciting a behavioral response to an individual over a brief period of time to be rare. In the event an individual is exposed to multiple sound sources that elicit a behavioral response (e.g., disruption of feeding) in a short amount of time, we do not expect these exposures to have fitness consequences as individuals will resume

feeding upon cessation of the sound exposure and unconsumed prey will still be available in the environment.

As noted in Southall et al. (Southall et al. 2007b), substantive behavioral reactions to noise exposure (such as disruption of critical life functions, displacement, or avoidance of important habitat) are considered more likely to be significant if they last more than 24 hours, or recur on subsequent days. Major training exercises conducted in the MITT Action Area can last several weeks, and during those exercises there may be periods of continuous sonar use. Not every major training exercise has anti-submarine warfare events where sonar is used. However, even the longest periods of "continuous" active sonar use rarely last longer than 12 hours, and active sonar use is not truly continuous because a sonar system is actively transmitting a small portion of the time (once per minute for approximately 10 seconds). For Navy active sonar use, a period of concentrated, near continuous anti-submarine warfare sonar use means that sound energy is being put in the water nearly 2 percent of the time. Sonar sound is not transmitting when trying to listen for returns of a detection of a submarine or contact of something else in the water column. Vessels equipped with the most powerful sonar systems would also generally be moving at speeds of 10 to15 knots separated in distances when using active sonar. Thus, even during major training exercises, it is unlikely that a specific geographic area or water column would be ensonified at high levels for prolonged periods of time, which could increase the risk of significant behavioral responses or repeated disturbances in close temporal proximity. Even if sound exposure were to be concentrated in a relatively small geographic area over a long period of time (e.g., days or weeks during major training exercises), we would expect that some individual whales would most likely respond by temporarily avoiding areas where exposures to acoustic stressors are at higher levels (e.g., greater than 120 dB). For example, Goldbogen et al. (2013) indicated some horizontal displacement of deep foraging blue whales in response to simulated MFA sonar. However, given these animal's mobility and large ranges, we would expect these individuals to temporaily select alternative foraging sites nearby until the exposure levels in their initially selected foraging area have decreased. Therefore, even temporary displacement from initially selected foraging habitat is not expected to impact the fitness of any individual animals because we would expect similar foraging to be available in close proximity. Because we do not expect any fitness consequences from any individual animals, we do not expect any population level effects from these behavioral responses.

On a related point, for purposes of this Opinion, we assume that the Navy's activities and associated impacts will continue into the reasonably foreseeable future at the annual levels discussed herein. This raises the question of whether the annual instances of modeled TTS or behavioral disturbances could indirectly lead to more serious aggregate or long-term impacts over time. Under certain conditions, chronic exposure to acoustic sources or other stimuli that can cause individual stress or behavioral responses can also lead to additional long-term adverse impacts. For example, investigators concluded that gray whales and humpback whales abandoned some of their coastal habitat in California and Hawaii, respectively, because of persistent underwater noise associated with extensive vessel traffic (Gard 1974) (Reeves 1977) (Salden 1988). Another study of terrestrial mammals suggests that while short-term stress responses are often beneficial, conditions of chronic or long-term stress can lead to adverse physiological effects (Romero, et al. 2007). However, because acoustic disturbances caused by

Navy sonar and explosives are short-term, intermittent, and (in the case of sonar) transitory, even during major training exercises, we would not expect the Navy's activities to create conditions of long-term, continuous underwater noise leading to habitat abandonment or long-term hormomal or physicological stress responses in marine mammals. Moreover, as discussed previously, Navy testing and training activities, including the use of MFA sonar, have been ongoing in the MITT Action Area for decades, and there is no evidence that the activities have caused blue whales or other listed species evaluated in this Opinion to abandon important habitat or any other severe adverse impacts.

Further, recent evidence indicates that the Eastern North Pacific blue whale population, which includes blue whales in Southern California, has likely reached carrying capacity (Monnahan et al. 2014). As stated previously, Navy training and testing activities in that area as with similar activities in the MITT Action Area, include the use of MFA sonar, and have been ongoing for decades. Therefore, any potential temporary behavioral impacts on blue whales from the use of MFA during Navy training and testing activities in the MITT Action Area are also likely to have not prevented the recovery of the blue whales throughout its range. The TTS and behavioral response estimates may change from year to year, which could mean an increase in the number of individual animals exposed per year or an increase in the number of times per year some animals are exposed. However, the severity of individual responses, and the consequences of those responses on the fitiness of affected individuals, is not expected to change.

Establishing a causal link between anthropogenic noise, animal communication, and individual impacts as well as population viability is difficult to quantify and assess (McGregor 2013) (Read et al. 2014). It is difficult to assess the effects of sounds individually and cumulatively on marine species because a number of factors can influence these effects including: indirect effects, age class, prior experience, behavioral state at the time of exposure, and that responses may be influenced by other non-sound related factors (Ellison et al. 2011; Goldbogen et al. 2013; Kight and Swaddle 2011; McGregor 2013; Williams et al. 2014) (Read et al. 2014). However, although there is significant uncertainty, based upon the available evidence and the foregoing analysis, we conclude that continuation of annual modeled instances of TTS and behavioral disturances into the reasonably foreseeable future is unlikely to cause aggregate or long-term adverse effects on blue whales, such as abandonment of important habitat or adverse physiological effects resulting from chronic or long-term stress.

Non-impulsive acoustic stressors from Navy training activities conducted during five-year period of proposed MMPA Rule and into the reasonably foreseeable future are not likely to reduce the viability or recovery of these populations. We anticipate temporary behavioral responses and TTS, but do not anticipate any injury or mortality from acoustic stressors. We do not anticipate those behavioral responses to result in fitness consequences to any individuals and therefore, we do not expect acoustic stressors to result in substantial changes in reproduction, numbers, or distribution of these populations. This conclusion is further supported by Monnahan et al. (2014) which concluded that the ENP blue whale population has likely reached carrying capacity despite decades of Navy training and testing activities, including MFA sonar, in the Hawaii and Southern California Training Ranges.

6.8.3.2.2 Fin Whale

Except as provided herein, our analysis of the modeled TTS and behavioral responses for blue whales applies equally to fin whales. Fin whales are not likely to respond to high-frequency sound sources associated with the proposed training and testing activities because of their hearing sensitivities. While we recognize that animal hearing evolved separately from animal vocalizations and, as a result, it may be inappropriate to make inferences about an animal's hearing sensitivity from their vocalizations, we have no data on fin whale hearing so we assume that fin whale vocalizations are partially representative of their hearing sensitivities. Those vocalizations include a variety of sounds described as low frequency moans or long pulses in the 10 Hz to 100 Hz band (Edds 1988; Thompson and Friedl 1982b; Watkins 1981b). The most typical signals are very long, patterned sequences of tonal infrasonic sounds in the 15 Hz to 40 Hz range. Ketten (1997a) reports the frequencies of maximum energy between 12 Hz and 18 Hz. Short sequences of rapid calls in the 30 to 90 Hz band are associated with animals in social groups (Clark personal observation and McDonald personal communication cited in Ketten 1997). The context for the 30 Hz to 90 Hz calls suggests that they are used to communicate but do not appear to be related to reproduction. Fin whale moans within the frequency range of 12.5 Hz to 200 Hz, with pulse duration up to 36 seconds, have been recorded off Chile (Cummings and Thompson 1994). The whale produced a short, 390 Hz pulse during the moan.

Results of studies on blue whales (Goldbogen et al. 2013) (Southall et al. 2011a), which have similar auditory physiology compared to fin whales, indicate that some individuals hear some sounds in the mid-frequency range and exhibit behavioral responses to sounds in this range depending on received level and context. However, as described in Section 6.8.3.2.1, regarding the response of blue whales to MFA sonar, we expect any behavioral response to be temporary and to not result in any fitness consequences to individual whales. Without more specific information, we assume the response of fin whales to TTS to be similar to that of blue whales. Additionally, several fin whales were tagged during the Southern California-10 BRS and no obvious responses to the controlled exposure to a mid-frequency sound source were detected by the visual observers or in the initial tag analysis (Southall et al. 2011a).

Further, work by Moore and Barlow (2011) indicate that since 1991, there is strong evidence of increasing fin whale abudance in the California Current area, which includes the Southern California Range Complex, an area in which Navy training and testing activities, including the use of MFA sonar, have been ongoing for decades. The authors predict continued increases in fin whale numbers over the next decade in that area, and that perhaps fin whale densities are reaching "current ecosystem limits." This indicates that any potential temporary behavioral impacts on fin whales from the use of MFA during Navy training and testing activities have not prevented fin whale numbers from increasing and potentially nearing ecosystem limits in Southern California. Since training and testing activities in the MITT Action Area are similar to those in Southern California, we would expect the effects to be similar in the MITT Action Area and thus not a limiting factor in the recovery of fin whales. The TTS and behavioral response estimates may change over baseline conditions from year to year, which could mean an increase in the number of individual animals exposed per year or an increase in the number of times per year some animals are exposed. However, the severity of individual responses, and the

consequences of those responses on the fitiness of affected individuals, is not expected to change.

Non-impulsive acoustic stressors from Navy training exercises and testing activities conducted during the five-year year period of the proposed MMPA Rule and into the reasonably foreseeable future are not likely to significantly interact (exposure and response) with a sufficient number of fin whales to reduce the viability or recovery of these populations. We anticipate temporary behavioral responses, but do not anticipate any injury or mortality from acoustic stressors. Therefore, we do not anticipate those behavioral responses to result in substantial changes in reproduction, numbers, or distribution of these populations.

6.8.3.2.3 Humpback Whale

Except as provided herein, our analysis of the modeled TTS and behavioral responses for blue whales applies equally to humpback whales. Humpback whales are not likely to respond to high-frequency sound sources associated with the proposed training exercises and testing activities because of their hearing sensitivities. We recognize animal hearing evolved separately from animal vocalizations and, as a result, it may be inappropriate to make inferences about an animal's hearing sensitivity from their vocalizations. However, we have no data on humpback whale hearing so we assume that humpback whale vocalizations are partially representative of their hearing sensitivities. As discussed in the *Status of Listed Resources* narrative for humpback whales, these whales produce a wide variety of sounds.

Humpback whales vocalize less frequently in their summer feeding areas than in their winter ranges at lower latitudes. Feeding groups produce distinctive sounds ranging from 20 Hz to 2 kHz, with median durations of 0.2 to 0.8 seconds and source levels of 175 to 192 dB (Thompson et al. 1986). These sounds are attractive and appear to rally animals to the feeding activity (D'Vincent et al. 1985; Sharpe and Dill 1997). To summarize, humpback whales produce at least three kinds of sounds:

1. Complex songs with components ranging from 20Hz to 4 kHz with estimated source levels from 144 to 174 dB; these are mostly sung by males on the breeding grounds (Payne and McVay 1971; Winn et al. 1970)

2. Social sounds in the breeding areas that extend from 50Hz to more than 10 kHz with most energy below 3 kHz (Richardson et al. 1995c; Tyack and Whitehead 1983); and

3. Feeding area vocalizations that are less frequent, but tend to be 20Hz to 2 kHz with estimated source levels in excess of 175 dB re 1 µPa-m (Richardson et al. 1995c; Thompson et al. 1986). Sounds often associated with possible aggressive behavior by males (Silber 1986; Tyack 1983) are quite different from songs, extending from 50 Hz to 10 kHz (or higher), with most energy in components below 3 kHz. These sounds appear to have an effective range of up to 9 km (Tyack and Whitehead 1983).

Au et al. (2006b) conducted field investigations of humpback whale songs that led these investigators to conclude that humpback whales have an upper frequency limit reaching as high as 24 kHz. Based on this information, it is reasonable to assume that the active mid-frequency

sonar the U.S. Navy uses during active sonar training exercises and testing activities in the MITT Action Area are within the hearing and vocalization ranges of humpback whales. There is limited information on how humpback whales are likely to respond upon being exposed to mid-frequency active sonar (most of the information available addresses their probable responses to low-frequency active sonar or impulsive sound sources). Maybaum (Maybaum 1993) conducted sound playback experiments to assess the effects of mid-frequency active sonar on humpback whales in Hawaiian waters. Specifically, she exposed focal pods to sounds of a 3.3-kHz sonar pulse, a sonar frequency sweep from 3.1 to 3.6 kHz, and a control (blank) tape while monitoring their behavior, movement, and underwater vocalizations. The two types of sonar signals differed in their effects on the humpback whales, although the whales exhibited avoidance behavior when exposed to both sounds. The whales responded to the sounds by increasing their distance from the sound; however, the frequency or duration of their dives or the rate of underwater vocalizations did not change. Similar to the conclusions drawn in Section 6.8.3.2.1 regarding responses of blue whales to MFA sonar, we expect any behavioral response to be temporary and to not result in any fitness consequences to individual humpback whales. Without more specific information, we assume the response of humpback whales to TTS to be similar to that of blue whales.

Humpback whales have been known to react to low frequency industrial noises at estimated received levels of 115 to 124 dB (Malme et al. 1985), and to calls of other humpback whales at received levels as low as 102 dB (Frankel et al. 1995). Malme et al. (1985) found no clear response to playbacks of drill ship and oil production platform noises at received levels up to 116 dB re 1 Pa. Studies of reactions to airgun noises were inconclusive (Malme et al. 1985). Humpback whales on the breeding grounds did not stop singing in response to underwater explosions (Payne and McVay 1971). Humpback whales on feeding grounds did not alter short-term behavior or distribution in response to explosions with received levels of about 150 dB re 1 Pa/Hz at 350 Hz (Lien et al. 1993; Todd et al. 1996b). However, at least two individuals were probably killed by the high-intensity, impulse blasts and had extensive mechanical injuries in their ears (Ketten et al. 1993; Todd et al. 1996b). The explosions may also have increased the number of humpback whales entangled in fishing nets (Todd et al. 1996b). Frankel and Clark (1998) showed that breeding humpbacks showed only a slight statistical reaction to playbacks of 60 to 90 Hz sounds with a received level of up to 190 dB. Although these studies have demonstrated that humpback whales will exhibit short-term behavioral reactions to boat traffic and playbacks of industrial noise, the long-term effects of these disturbances on the individuals exposed to them are not known. Humpback whales in Stellwagen Bank National Marine Sanctuary reduced their calling rates coincident with an Ocean Acoustic Waveguide Remote Sensing experiment 200 km away with FM pulses centered at 415, 734, and 949 Hz (Risch et al. 2012). However, Gong et al. (2014), disputes these findings, suggesting that Risch et al. (2012) mistakes natural variations in humpback whale song occurrence for changes caused by OAWRS activity approximately 200 km away. Risch et al. (2014) responded to Gong et al. (2014) and highlighted the context-dependent nature of behavioral responses to acoustic stressors.

The overall abundance of humpback whales in the south Pacific has continued to increase and is now greater than some pre-whaling abundance estimates. The TTS and behavioral response estimates may change from year to year over baseline conditions, which could mean an increase

in the number of individual animals exposed per year or an increase in the number of times per year some animals are exposed. However, the severity of individual responses, and the consequences of those responses on the fitness of affected individuals, is not expected to change.

Acoustic stressors from Navy training and testing activities conducted during the five-year period of the proposed MMPA Rule and into the reasonably foreseeable future are not likely to significantly interact (exposure and response) with a sufficient number of humpback whales to reduce the viability of these populations or adversely impact species recovery. We anticipate temporary behavioral responses, but do not anticipate any injury or mortality from acoustic stressors. Therefore, we do not anticipate those behavioral responses to result in substantial changes in reproduction, numbers, or distribution of these populations.

6.8.3.2.4 Sei Whale

Except as provided herein, our analysis of the modeled TTS and behavioral responses for blue whales applies equally to sei whales. Like blue and fin whales, sei whales are not likely to respond to high-frequency sound sources associated with the proposed training exercises and testing activities because of their hearing sensitivities. As discussed in the *Status of Listed Resources* section of this Opinion, we have no specific information on the hearing sensitivity of sei whales. Based on their anatomical and physiological similarities to both blue and fin whales, we assume that the hearing thresholds of sei whales will be similar as well and will be centered on low-frequencies in the 10 to 200 Hz.

Results of studies on blue whales (Goldbogen et al. 2013) (Southall et al. 2011a), which have similar auditory physiology compared to sei whales, indicate that some individuals hear some sounds in the mid-frequency range and exhibit behavioral responses to sounds in this range depending on received level and context. However, as described in Section 6.8.3.2.1, regarding the response of blue whales to MFA sonar, we expect any behavioral response to be temporary and to not result in any fitness consequences to individual whales. Without more specific information, we assume the response of fin whales to TTS to be similar to that of blue whales (see Section 6.8.3.2.1). The TTS and behavioral response estimates may change from year to year over baseline conditions, which could mean an increase in the number of individual animals exposed per year or an increase in the number of times per year some animals are exposed. However, the severity of individual responses, and the consequences of those responses on the fitness of affected individuals, is not expected to change.

Acoustic stressors from Navy training exercises and testing activities conducted during the five-year period of the proposed MMPA Rule and into the reasonably foreseeable future are not likely to significantly interact (exposure and response) with a sufficient number of sei whales to reduce the viability of these population ot their ability to recover. We anticipate temporary behavioral responses, but do not anticipate any injury or mortality from acoustic stressors. Therefore, we do not anticipate those behavioral responses to result in substantial changes in reproduction, numbers, or distribution of these populations.

6.8.3.2.5 Sperm Whale

Temporary Threshold Shift (TTS) - As mentioned previously, TTS can last from a few minutes to days, be of varying degree, and occur across various frequency bandwidths, all of which determine the severity of the impacts on the affected individual, which can range from minor to more severe. The TTS sustained by an animal is primarily classified by three characteristics:

1. Frequency—Available data (of midfrequency hearing specialists exposed to mid- or high-frequency sounds; (Southall et al. 2007b)) suggest that most TTS occurs in the frequency range of the source up to one octave higher than the source (with the maximum TTS at ½ octave above). The more powerful mid-frequency sources used have center frequencies between 3.5 kHz and 8 kHz and the other unidentified mid-frequency sources are, by definition, less than 10 kHz, which suggests that TTS induced by any of these mid frequency sources would be in a frequency band somewhere between approximately 2 and 20 kHz. Although there is no published audiogram for sperm whales, sperm whales would be expected to have good, high frequency hearing because their inner ear resembles that of most dolphins, and appears tailored for ultrasonic (>20 kHz) reception (Ketten 1994). The only data on the hearing range of sperm whales are evoked potentials from a stranded neonate, which suggest that neonatal sperm whales respond to sounds from 2.5 kHz to 60 kHz. Sperm whales vocalize in high- and mid-frequency ranges; most of the energy of sperm whales clicks is concentrated at 2 kHz to 4 kHz and 10 kHz to 16 kHz. Other studies indicate sperm whales' wide-band clicks contain energy between 0.1 kHz and 20 kHz (Goold and Jones 1995; Weilgart and Whitehead 1993b). Ridgway and Carder (Ridgway and Carder 2001) measured low-frequency, high amplitude clicks with peak frequencies at 500 Hz to 3 kHz from a neonate sperm whale.The full range of functional hearing for the sperm whale is estimated to occur between approximately 150 Hz and 160 kHz, placing them among the group of cetaceans that can hear mid-frequency sounds (Southall et al. 2007b). Therefore, TTS associated with mid-frequency sonar could conceivably interfere with an animal's ability to hear vocalizations or most other biologically important sounds.

2. Degree of the shift (i.e., how many dB is the sensitivity of the hearing reduced by)—Generally, both the degree of TTS and the duration of TTS will be greater if the marine mammal is exposed to a higher level of energy (which would occur when the peak dB level is higher or the duration is longer). The threshold for the onset of TTS was discussed previously in this document. An animal would have to approach closer to the source or remain in the vicinity of the sound source appreciably longer to increase the received SEL, which would be difficult considering the lookouts, the sightability of sperm whales, and the nominal speed of an active sonar vessel (10 to 15 knots). In the TTS studies, some using exposures of almost an hour in duration or up to 217 SEL, most of the TTS induced was 15 dB or less, though Finneran et al. (2007) induced 43 dB of TTS with a 64-second exposure to a 20 kHz source. However, mid-frequency active sonar emits a nominal ping every 50 seconds, and incurring those levels of TTS is highly unlikely.

3. Duration of TTS (recovery time)—In the TTS laboratory studies, some using exposures of almost an hour in duration or up to 217 SEL, almost all individuals recovered within 1

> day (or less, often in minutes), though in one study (Finneran et al. 2007), recovery took 4 days. Based on the range of degree and duration of TTS reportedly induced by exposures to non-pulse sounds of energy higher than that to which frees wimming marine mammals in the field are likely to be exposed during mid-frequency/high-frequency active sonar training exercises in the Action Area, it is unlikely that sperm whale or other listed cetaceans would ever sustain a TTS from MFAS that alters their sensitivity by more than 20 dB for more than a few days (and any incident of TTS would likely be far less severe due to the short duration of the majority of the exercises and the speed of a typical vessel). Also, because of the short distance within which animals would need to approach the sound source, it is unlikely that animals would be exposed to the levels necessary to induce TTS in subsequent time periods such that their recovery is impeded.

Therefore, for sperm whales and other ESA-listed marine mammals analyzed in this Opinion, even though the modeled TTS estimates may change from year to year over baseline conditions including potential increases of exposure, NMFS does not anticipate TTS of a long duration or severe degree to occur as a result of exposure to mid- or high-frequency active sonar utilized in the MITT Action Area.

Behavioral Responses - The Navy's acoustic analysis indicates that exposures of sperm whales to sound levels are likely to result in behavioral harassment from sonar or other active acoustic stressors during training and testing activities. These exposure instances are anticipated to be in the form of behavioral harassment and no injurious takes of sperm whales from sonar, other active acoustic stressors, or explosives are anticipated. Sperm whales have shown resilience to acoustic and human disturbance, although they may react to sound sources and activities within a few kilometers. Sperm whales that are exposed to activities that involve the use of sonar and other active acoustic sources may alert, ignore the stimulus, avoid the area by swimming away or diving, or display aggressive behavior. Some (but not all) sperm whale vocalizations might overlap with the mid-frequency active sonar or high frequency active sonar frequency ranges, which could temporarily decrease an animal's sensitivity to the calls of conspecifics or returning echolocation signals. However, we do not anticipate TTS of a long duration or severe degree to occur as a result of exposure to these sonar sources. The majority of exposure instances are expected to be in the form of mild responses.

Vocal changes in response to anthropogenic noise can occur across the range of sound production modes used by marine mammals, such as whistling, echolocation click production, calling, and singing. Changes may result in response to a need to compete with an increase in background noise or may reflect an increased vigilance or startle response. Odontocetes such as killer whales off the northwestern coast of the U.S. have been observed to increase the duration of primary calls once a threshold in observing vessel density (e.g., whale watching) was reached, which has been suggested as a response to increased masking noise produced by the vessels (Foote et al. 2004). In contrast, both sperm and pilot whales potentially ceased sound production during the Heard Island feasibility test (Bowles et al. 1994), although it cannot be absolutely determined whether the inability to acoustically detect the animals was due to the cessation of sound production or the displacement of animals from the area.

There is some evidence of disruptions of clicking and behavior from sonars (Goold 1999a; Watkins 1985), pingers (Watkins and Schevill 1975a), the Heard Island Feasibility Test (Bowles et al. 1994), and the Acoustic Thermometry of Ocean Climate (Costa et al. 1998). Sperm whales have been observed to frequently stop echolocating in the presence of underwater pulses made by echosounders (Watkins and Schevill 1975a). Goold (1999a) reported six sperm whales that were driven through a narrow channel using ship noise, echosounder, and fish finder emissions from a flotilla of 10 vessels. Watkins and Schevill (1975a) showed that sperm whales interrupted click production in response to pinger (6 to 13 kHz) sounds. They also stopped vocalizing for brief periods when codas were being produced by other individuals, perhaps because they can hear better when not vocalizing themselves (Goold and Jones 1995).

Sperm whales stop vocalizing for brief periods when codas are being produced by other individuals, perhaps because they can hear better when not vocalizing themselves (Goold and Jones 1995). Results of experimental playbacks of killer whale sounds to five individual male sperm whales in the Norwegian Sea showed that, rather than diving away from the perceived predator, sperm whales responded by interrupting their foraging or resting dives and returning to the surface, changing their vocal production, and initiating a surprising degree of social behavior (Cure et al. 2013).

Other studies identify instances in which sperm whales did not respond to anthropogenic sounds. Sperm whales did not alter their vocal activity when exposed to levels of 173 dB re 1 µPa from impulsive sounds produced by 1 g TNT detonators (Madsen and Mohl 2000). Richardson et al. (1995c) citing a personal communication with J. Gordon suggested that sperm whales in the Mediterranean Sea continued calling when exposed to frequent and strong military sonar signals. When Andre et al. (1997) exposed sperm whales to a variety of sounds to determine what sounds may be used to scare whales out of the path of vessels, sperm whales were observed to have startle reactions to 10 kHz pulses (180 dB re 1 µPa at the source), but not to the other sources played to them.

Published reports identify instances in which sperm whales have responded to an acoustic source and other instances in which they did not appear to respond behaviorally when exposed to seismic surveys. Mate et al. (1994) reported an opportunistic observation of the number of sperm whales to have decreased in an area after the start of airgun seismic testing. However, Davis et al. (2000b) noted that sighting frequency did not differ significantly among the different acoustic levels examined in the northern Gulf of Mexico, contrary to what Mate et al. (1994) reported. Sperm whales may also have responded to seismic airgun sounds by ceasing to call during some (but not all) times when seismic pulses were received from an airgun array >300 km away (Bowles et al. 1994).

A study offshore of northern Norway indicated that sperm whales continued to call when exposed to pulses from a distant seismic vessel. Received levels of the seismic pulses were up to 146 dB re 1 µPa peak-to-peak (Madsen et al. 2002). Similarly, a study conducted off Nova Scotia that analyzed recordings of sperm whale sounds at various distances from an active seismic program did not detect any obvious changes in the distribution or behavior of sperm whales (McCall-Howard 1999). Data from vessel-based monitoring programs in United Kingdom waters suggest that sperm whales in that area may have exhibited some changes in

behavior in the presence of operating seismic vessels (Stone 1997; Stone 1998; Stone 2000; Stone 2001; Stone 2003). However, the compilation and analysis of the data led the author to conclude that seismic surveys did not result in observable effects to sperm whales (Stone 2003). The results from these waters seem to show that some sperm whales tolerate seismic surveys.

Sperm whales have been observed to frequently stop echolocating in the presence of underwater pulses produced by echosounders and submarine sonar (Watkins 1985; Watkins and Schevill 1975a). They also stop vocalizing for brief periods when codas are being produced by other individuals, perhaps because they can hear better when not vocalizing themselves (Goold and Jones 1995). Because they spend large amounts of time at depth and use low frequency sound sperm whales are likely to be susceptible to low frequency sound in the ocean (Croll et al. 2001b). Furthermore, because of their apparent role as important predators of mesopelagic squid and fish, changes in their abundance could affect the distribution and abundance of other marine species.

Disruption of feeding behavior can be difficult to correlate with anthropogenic sound exposure. Responses may vary depending on the behavioral state of the individual or group of animals. For example, sperm whales engaged in foraging dives did not abandon dives when exposed to distant signatures of seismic airguns (Madsen et al. 2006). Conversely, preliminary results of controlled playback of sonar may indicate feeding/foraging disruption of killer whales and sperm whales (Miller et al. 2011).

Richardson et al. (1995c) noted that avoidance (temporary displacement of an individual from an area) reactions are the most obvious manifestations of disturbance in marine mammals. It is qualitatively different from the startle or flight response, but also differs in the magnitude of the response (i.e., directed movement, rate of travel, etc.). Oftentimes avoidance is temporary, and animals return to the area once the noise has ceased. In the Caribbean, sperm whales avoided exposure to mid-frequency submarine sonar pulses, in the range of 1000 Hz to 10,000 Hz (IWC 2005).

These studies suggest that the behavioral responses of sperm whales to anthropogenic sounds are highly variable, but do not appear to result in the death or injury of individual whales or result in reductions in the fitness of individuals involved. Responses of sperm whales to anthropogenic sounds probably depend on the age and sex of animals being exposed, as well as other factors. There is evidence that many individuals respond to certain sound sources, provided the received level is high enough to evoke a response, while other individuals do not.

The TTS and behavioral response estimates may change from year to year over baseline conditions, which could mean an increase in the number of individual animals exposed per year or an increase in the number of times per year some animals are exposed. However, the severity of individual responses, and the consequences of those responses on the fitiness of affected individuals, is not expected to change.

Non-Impulsive acoustic stressors from Navy training exercises and testing activities conducted during the five-year period of the proposed MMPA Rule and into the reasonably foreseeable future are not likely to significantly interact (exposure and response) with a sufficient number of

sperm whales to reduce the viability of these populations or their ability to recovery. We anticipate behavioral responses, but do not anticipate any injury or mortality from acoustic stressors. Therefore, we do not anticipate those behavioral responses to result in substantial changes in reproduction, numbers, or distribution of these populations.

6.8.4 Effects of Non-Impulsive Acoustic Stressors - Sea Turtles

For this consultation, we considered exposure estimates from the Navy Acoustic Effects Model at several output points for sea turtles.

6.8.4.1 Unprocessed Exposures to Non-Impulsive Acoustic Stressors During Training Activities

Sea turtles that reside in the Action Area may be exposed several times throughout the year to sound from sonar and other active acoustic sources. Exposures to sonar and other active acoustic sources in open water areas would be intermittent and geographically variable. The Navy model output indicates that green, hawksbill, loggerhead, and leatherback sea turtles would be exposed to sonar at levels that may rise to the level of behaviroral take and TTS.

Navy model output estimates of sea turtes that will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities throughout the year are summarized in Table 56 and discussed below.

Table 56. Model-Predicted Exposures of Sea Turtles to Non-Impulsive Sound During Training Activities

Species	Number of Model-Predicted Exposures >120 dB Per Year
Green Turtle	12,564
Hawksbill Turtle	383
Leatherback Turtle	99
Loggerhead Turtle	94

Green sea turtle. The NAEMO provided an unprocessed estimate of 12,564 green sea turtle exposure events annually to non-impulsive sounds associated with annual training at levels greater than 120 dB SPL. Eighty-two (82) percent of the estimated 12,564 green sea turtle exposures will result from Marine Air Ground Task Force Exercise (Amphibious) while 11 percent will result from TRACKEX/TORPEX – Surface.

Hawksbill sea turtle. The NAEMO provided an unprocessed estimate of 383 hawksbill sea turtle exposure events annually to non-impulsive sounds associated with annual training at levels greater than 120 dB SPL. Forty-seven (47) percent of the estimated 383 hawksbill sea turtle exposures will result from Marine Air Ground Task Force Exercise (Amphibious) while 19 percent will result from TRACKEX/TORPEX – Surface, 17 percent from Joint Multi-Strike Group Exercises and 12 percent from Joint Expeditionary Exercises .

Leatherback sea turtle. The NAEMO provided an unprocessed estimate of 99 leatherback sea turtle exposure events annually to non-impulsive sounds associated with annual training at levels greater than 120 dB SPL. Thirty (30) percent of the estimated 99 leatherback sea turtle exposures

will result from Joint Multi-Strike Group Exercises while 28 percent will result from Joint Expeditionary Exercises, 20 percent from TRACKEX/TORPEX – Surface and 15 percent from Marine Air Ground Task Force Exercise (Amphibious).

Loggerhead sea turtle. The NAEMO provided an unprocessed estimate of 94 loggerhead sea turtle exposure events annually to non-impulsive sounds associated with annual training at levels greater than 120 dB SPL. Twenty-six (26) percent of the estimated 94 loggerhead sea turtle exposures will result from Joint Multi-Strike Group Exercises while 26 percent will result from Joint Expeditionary Exercises, 22 percent from TRACKEX/TORPEX – Surface and 19 percent from Marine Air Ground Task Force Exercise (Amphibious).

6.8.4.2 Unprocessed Exposures to Non-impulsive Acoustic Stressors During Testing Activities

Navy model output estimates of sea turtes that will be exposed to sonar and other non-impulsive acoustic stressors associated with training activities throughout the year are summarized in Table 57 and discussed below.

Table 57. Model-Predicted Exposures of Sea Turtles to Non-Impulsive Sound During Testing Activities

Species	Number of Model-Predicted Exposures >120 dB Per Year
Green Turtle	20,848
Hawksbill Turtle	800
Leatherback Turtle	144
Loggerhead Turtle	131

Green sea turtle. The NAEMO provided an unprocessed estimate of 20,848 green sea turtle exposure events annually to non-impulsive sounds associated with annual testing activities at levels greater than 120 dB SPL. Eighty-five (85) percent of the estimated 20,848 green sea turtle exposures will result from ASW Mission Package Testing while 7 percent will result from At-Sea Sonar Testing.

Hawksbill sea turtle. The NAEMO provided an unprocessed estimate of 800 hawksbill sea turtle exposure events annually to non-impulsive sounds associated with annual testing activities at levels greater than 120 dB SPL. Sixty-nine (69) percent of the estimated 800 hawksbill sea turtle exposures will result from ASW Mission Package Testing while 10 percent will result from At-Sea Sonar Testing and 15 percent from Anti-Submarine Warfare Tracking Test – Maritime Patrol Aircraft.

Leatherback sea turtle. The NAEMO provided an unprocessed estimate of 144 leatherback sea turtle exposure events annually to non-impulsive sounds associated with annual testing activities at levels greater than 120 dB SPL. Fifty-five (55) percent of the estimated 144 leatherback sea turtle exposures will result from ASW Mission Package Testing while 39 percent will result from Anti-Submarine Warfare Tracking Test – Maritime Patrol Aircraft.

Loggerhead sea turtle. The NAEMO provided an unprocessed estimate of 131 loggerhead sea turtle exposure events annually to non-impulsive sounds associated with annual testing activities

at levels greater than 120 dB SPL. Sixty (60) percent of the estimated 131 loggerhead sea turtle exposures will result from ASW Mission Package Testing while 34 percent will result from Anti-Submarine Warfare Tracking Test – Maritime Patrol Aircraft.

6.8.4.3 Processed Exposures to Non-Impulsive Acoustic Stressors During Training and Testing Activities

In the previous sections we assessed, that the Navy model output indicates approximately 33,412 unprocessed instances of green sea turtle exposures, 1,182 unprocessed instances of hawksbill sea turtle exposures, 243 unprocessed instances of leatherback sea turtle exposures, and 224 unprocessed instances of loggerhead sea turtle exposures each year resulting from non-impulsive sound (sonar) from training and testing activities at levels equal to or greater than 120 dB which is the level at which we would expect an onset of more significant behavioral responses.

Processed exposures of sea turtles to acoustic stressors from training and testing activities predicted by the NAEMO are shown below in Table 58. The exposure estimates for each alternative represent the total number of exposures and not necessarily the number of individuals exposed, as a single individual may be exposed multiple times over the course of a year. The predicted acoustic impacts do not take into account avoidance behavior or mitigation measures, such as establishing shut-down zones for certain sonar systems. Again, since TTS and PTS criteria for sea turtles is 17 dB below what it is supposed to be, the estimates provided are overestimates (See Section 6.3.8).

Table 58. Annual Total Model-Predicted Impacts on Sea Turtles from Training and Testing Activities Using Sonar and Other Active Acoustic Sources

Sea Turtle Species	Temporary Threshold Shift	Permanent Threshold Shift
Green sea turtle	251	0
Hawksbill sea turtle	17	0
Leatherback sea turtle	12	0
Loggerhead sea turtle	15	0

The Navy model may over-predict acoustic impacts because it does not consider avoidance and the criteria to predict impacts. The TTS exposures could temporarily affect perception of sound within a limited frequency range.

6.8.4.4 Response of Sea Turtles to Non-impulsive Acoustic Stressors During Training and Testing Activities

Little is known about how sea turtles use sound in their environment. Based on knowledge of their sensory biology (Moein Bartol and Ketten 2006) (Moein Bartol and Musick 2003), sea turtles may be able to detect objects within the water column (e.g., vessels, prey, predators) via some combination of auditory and visual cues. However, research examining the ability of sea turtles to avoid collisions with vessels shows they may rely more on their vision than auditory cues (Hazel et al. 2007). Similarly, while sea turtles may rely on acoustic cues to identify nesting beaches, they appear to rely on other non-acoustic cues for navigation, such as magnetic fields (Lohmann and Lohmann 1996a) (Lohmann and Lohmann 1996b) and light (Avens and Lohmann 2003). Additionally, they are not known to produce sounds underwater for communication.

Further, although the information on the hearing capabilities of sea turtles is limited, the information available suggests that the auditory capabilities of sea turtles are centered in the low-frequency range (<2 kHz) (Bartol et al. 1999b; Dow Piniak et al. 2012; Lenhardt et al. 1983; Lenhardt et al. 1994a; Martin et al. 2012; O'Hara and Wilcox 1990; Ridgway et al. 1969), with greatest sensitivity below 1 kHz. A more recent review on sea turtle hearing and sound exposure indicated that sea turtles detect sounds at less than 1000Hz and therefore would not be affected by mid or high-frequency active sonar (Popper et al. 2014).

Similarly, a study on the effects of airguns on sea turtle behavior also suggests that sea turtles are most likely to respond to low-frequency sounds. McCauley et al. (2000) reported that green and loggerhead turtles will avoid air-gun arrays at 2 km and at 1 km with received levels of 166 dB re 1 μPa and 175 db re 1 μPa, respectively. The sea turtles responded consistently: above a level of approximately 166 dB re 1 μPa the turtles noticeably increased their swimming activity compared to non-airgun operation periods. Above 175 dB re 1 μPa mean squared pressure their behavior became more erratic possibly indicating the turtles were in an agitated state. A study conducted in the Mediterranean Sea found that of 164 loggerhead turtles observed, 57 percent responded to the firing of an air gun array (source level 252 dB re 1 μPa [peak]) by diving at or before their closest point of approach to the airguns, with dive probability decreasing with increasing distance from the airgun array (DeRuiter and Larbi Doukara 2012).

Acoustic stressors associated with the Navy's activities in the MITT Action Area have the ability to cause behavioral responses in sea turtles. The response of a sea turtle to an anthropogenic sound will depend on the frequency, duration, temporal pattern, and amplitude of the sound, as well as the animal's prior experience with the sound and the context in which the sound is encountered (i.e., what the animal is doing at the time of the exposure). Distance from the sound source and whether it is perceived as approaching or moving away could also affect the way a sea turtle responds. Potential behavioral responses to anthropogenic sound could include startle reactions, disruption of feeding, disruption of migration, changes in respiration, alteration of swim speed, alteration of swim direction, and area avoidance. Any disruptions are expected to be temporary in nature, with the animal resuming normal behaviors shortly after the exposure. To result in significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for the energy expended during evasion and any potential lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. Similarly, to result in significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for the energy expended during evasion rather than would have been incurred during normal migration, respiration, swimming speed, and swimming direction. There is no indication this is the case, particularly since foraging habitat would still be available in the environment following the cessation of acoustic exposure. Therefore, behavioral responses of sea turtles to acoustic stressors is unlikely to lead to fitness consequences and long-term implications for the population.

Although we assume that sea turtles in the vicinity of sonar might experience a TTS, it is not certain at what energy levels and received levels are necessary to induce threshold shifts. The

few studies completed on the auditory capabilities of sea turtles (adult green, loggerhead, and Kemp's ridley turtles) suggest that they could be capable of hearing low frequency sounds (Lenhardt 1994a; Moein et al. 1993; Ridgway et al. 1969). Ridgway et al. (Ridgway et al. 1969) reported maximal sensitivity for green turtles occurred at 300 to 400 Hz, with a rapid decline in sensitivity for lower and higher tones. Similarly, Moein et al. (Moein et al. 1993) reported a hearing range of about 250 to 1,000 Hz for loggerhead turtles, and Lenhardt (Lenhardt 1994a) stated that maximal sensitivity in sea turtles generally occurs in the range from 100 to 800 Hz. Calculated in-water hearing thresholds within the useful range appear to be high (e.g., about 160 to 200 dB re 1 µPa) (Lenhardt 1994a). Piniak et al. reported maximum sensitivity between 100 and 400 Hz in water (84 dB re: 1 µPa at 300 Hz) and 50 and 400 Hz in air (62 dB re: 20 µPa at 300 Hz) for leatherback sea turtle hatchlings (Piniak et al. 2012). In the absence of more specific information that could be used to determine the acoustic harassment range for sea turtles, the U.S. Navy assumed that frequencies >100 Hz (which are the acoustical harassment ranges predicted for odontocetes) would be conservative for sea turtles. Given that sea turtles do not rely on acoustic cues for most important life functions, it is anticipated that TTS will not result in fitness consequences to individuals or the populations to which they belong.

Non-impulsive acoustic stressors from Navy training and testing activities conducted during five-year period of the proposed MMPA rule and into the reasonably foreseeable future are likely to cause TTS to sea turtles in the MITT Action Area. However, there is no evidence that TTS results in energetic effects to individual sea turtles or would be likely to significantly reduce the viability of the population these individuals represent. Additionally, based on the analysis presented above, we do not anticipate any PTS, injury or mortality of sea turtles from non-impulsive acoustic stressors.

6.8.5 Effects of Non-Impulsive Acoustic Stressors - Scalloped Hammerhead Shark – Indo-Pacific DPS

This section discusses the effects of non-impulsive acoustic stressors on scalloped hammerhead sharks. Exposure of scalloped hammerhead sharks to acoustic stressors could not be quantitatively assessed due to limited information on species distribution and density in the Action Area. Scalloped hammerhead sharks are likely only capable of detecting sounds between 20 Hz and 1 kHz with the highest sensitivity in the lower end of this spectrum (Casper et al. 2003; Casper and Mann 2006; Myrberg Jr. 2001). As such, this species is only anticipated to detect and potentially be exposed to non-impulsive acoustic stressors below 1 kHZ, which the Navy defines as low-frequency sources. No low frequency sources will be used during training activities as part of the proposed action. As part of training activities, in port maintenance of sonar systems would occur within Inner Apra Harbor where anecdotal evidence suggests a scalloped hammerhead nursery may be present. However, the in-port and at-sea maintenance of surface ship sonar systems training are mid-frequency hull-mounted sonar systems. The in-port and at-sea maintenance of submarine sonar systems are mid- and high-frequency sonar systems. Therefore, these activities are unlikely to be detected by scalloped hammerhead sharks.

A combined total of 174 hours of low-frequency acoustic sources will be used per year during testing activities. Low-frequency sonar use may be part of the following testing activities: at-sea sonar testing, pierside integrated swimmer defense testing, and anti-submarine warfare mission package testing. Of these activities, the pierside integrated swimmer defense testing will occur in

Inner Apra Harbor, where exposure to scalloped hammerhead sharks is most likely. Pierside integrated swimmer defense testing includes non-impulsive acoustic energy from 180 to 200 dB at frequencies less than 1 kHz, suggesting that if juvenile or adult scalloped hammerhead sharks are present within Inner Apra Harbor, they could be exposed to non-impulsive acoustic energy at frequencies they can detect. Pierside integrated swimmer defense testing will occur for 28 days per year with intermittent periods of use of low-frequency sound.

The duration and intensity of low-frequency non-impulsive acoustic stressors and the lack of a swim bladder will likely minimize the effect this stressor has on scalloped hammerhead sharks. In studies of rainbow trout, low-frequency active sonar at 193 dB re 1 μPa^2 for up to 648 seconds did not cause mortality although up to a 25 dB threshold shift was observed when trout received a 400 Hz exposure (Popper et al. 2007). The threshold shift lasted at least 48 hours post-exposure. Exposure at this level also caused a rapid swimming behavioral response at the beginning of treatment. Although a threshold shift was observed it is noteworthy no noticeable morphological effects were observed to ear structures and fish appeared healthy and active throughout the end of the experimental period (1 week) (Popper et al. 2007).

Several shark species, including the oceanic silky shark (*Carcharhinus falciformis*) and coastal lemon shark (*Negaprion brevirostris*), have been observed withdrawing from pulsed low-frequency sounds played from an underwater speaker (Klimley and Myrberg 1979; Myrberg et al. 1978). Lemon sharks exhibited withdrawal responses to pulsed low to mid-frequency sounds (500 to 4,000 Hz) raised 18 dB at an onset rate of 96 dB/sec to a peak amplitude of 123 dB RL from a continuous level, just masking broadband ambient noise (Klimley and Myrberg 1979). In their study, lemon sharks withdrew from artificial sounds which included 10 pulses/second (continuous), 10 pulses/second (intermittent, and 15 to 7.5 decreasing pulses/second (intermittent).

Some sharks are attracted to pulsing LF sounds. Myrberg (2001) stated that sharks have demonstrated highest sensitivity to LF sound (40 to 800 Hz). Free-ranging sharks are attracted to sounds possessing specific characteristics including irregular pulsed, broadband frequencies below 80 Hz and transmitted suddenly without an increase in intensity thus resembling a struggling fish.

These signals, some "pulsed," are substantially different from the LFA sonar signals. Myrberg et al. (1978) reported that a silky shark withdrew 10 m (33 ft) from a speaker broadcasting a 150 to 600 Hz sound with a sudden onset and a peak SL of 154 dB. These sharks avoided a pulsed LF attractive sound when its sound level was abruptly increased by more than 20 dB. Other factors enhancing withdrawal were sudden changes in the spectral or temporal qualities of the transmitted sound. These results do not rule out that such sounds may have been harmful to them after habituation; the tests were not designed to examine that point. Klimley (unpublished data) also noted the increase in tolerance of lemon sharks during successive sound playback tests. The pelagic whitetip (*Carcharhinus longimanus*) also showed a withdrawal response during limited tests (Myrberg et al. 1978).

The precise expected response of scalloped hammerhead sharks to low-frequency acoustic energy is not completely understood due to a lack of sufficient experimental and observational

data for this species. However, given the signal type and level of exposure to the low frequency signals used in pierside swimmer defense testing activities and the lack of swim bladders in scalloped hammerhead sharks as discussed above, we do not expect significant responses (including TTS, PTS, injury or mortality) to low-frequency acoustic energy from pierside integrated swimmer defense testing. The most likely response of scalloped hammerhead sharks exposed to low-frequency sonar are minor temporary changes in their behavior including increased swimming rate, avoidance of the sound source, attraction to the sound source, or changes in orientation to the sound source, not rising to the level of take. Therefore, these behavioral responses will not have long term impacts to the individual, the population, or the DPS.

6.8.6 Effects of Non-Impulsive Acoustic Stressors – *Acropora globiceps*

Corals are not biologically capable of detecting noise except as vibrations of water particles caused by low frequency sounds. Non-impulsive acoustic stressor sources (sonar) are typically intiated from offshore activities where *Acropora globiceps* is not expected to occur. Non-impulsive acoustic stressors are of short duration and intermittent and even if detectable by corals, would not increase the likelihood of injury from significant disruption of breeding, feeding, or sheltering. Therefore, effects to ESA-listed corals from non-impulsive acoustic stressors are not reasonably expected to occur or will be insignificant.

6.8.7 Effects of Impulsive Acoustic Stressors – Cetaceans

As mentioned above, we considered exposure estimates from the Navy Acoustic Effects Model at two output points for marine mammals. First, the total number of ESA-listed species (animats) that would be exposed to acoustic sources greater than 120 dB prior to the application of a dose-response curve or criteria. We term these the "unprocessed" estimates. This estimate is the number of times individual animats or animals are likely to be exposed to the acoustic environment that is a result of training exercises and testing activities, regardless of whether they are "taken" as a result of that exposure. In most cases, the number of animals "taken" by an action would be a subset of the number of animals that are exposed to the action because (1) in some circumstances, animals might not respond to an exposure and (2) some responses may be negative for an individual animal without constituting a form of "take" (for example, some physiological stress responses only have fitness consequences when they are sustained and would only constitute a "take" as a result of cumulative exposure).

The second set of exposure estimates ("processed") of listed species were generated and processed using dose-response curves and criteria for temporary and permanent threshold shift developed by the Navy and NMFS' Permits Division for the purpose of identifying harassment pursuant to the MMPA and account for any mitigation and avoidance behaviors that may reduce instances of exposure at levels that might result in injury including PTS. The unprocessed impulsive sound exposure estimates do not consider standard mitigation actions that NMFS' Permits Division would require under the MMPA rule to avoid marine mammals or that the Navy proposes for marine mammals, nor did the unprocessed estimates consider any avoidance responses that might be taken by individual animals once they sense the presence of Navy vessels or aircraft.

The exposure and response analysis presented in this Opinion considers these exposure estimates on an annual basis, cumulatively over the five-year period, and cumulatively for the reasonably foreseeable future to derive a final estimate of anticipate levels of take by training activity and species.

Approximately 12,500 explosives would be used during training and testing activities per year and would occur in areas designated for use of explosives within the Action Area. Approximately 10,000 (or 80 percent) of the explosives used in the Action Area are in source class E1 (0.1 to 0.25 lb. NEW). Other than those on FDM, most detonations would typically occur beyond approximately 12 nm from shore, minimizing impacts near nesting beaches or coastal habitats for sea turtles. A small number of near-shore (within 3 nm) training activities could occur, potentially exposing some sea turtles approaching nesting beaches to impulse sounds over a short duration if the training occurred during nesting season or close to sea turtles nearshore habitats. However, the terrain of FDM does not provide any nesting beaches, therefore, effects are not expected. In water training and testing activities using lower NEW explosives (up to 10 lb. NEW) will occur at UNDET sites within Apra Harbor and the Piti Mine Neutralization Site and higher NEW explosives (up to 20 lb. NEW) at the Agat Bay Mine Neutralization Site.

The remaining activities utilizing explosive detonations would be restricted to portions of the Action Area that are farther than 12 nm from the shore.

6.8.7.1 Unprocessed Exposure to Impulsive Acoustic Stressors During Training Activities

Navy model output estimates of cetaceans that will be exposed to impulsive acoustic stressors associated with training activities throughout the year are summarized in Table 59 and discussed below.

Table 59. Model-Predicted, Unprocessed Exposures of Cetaceans to Impulsive Sound During Training Activities

Species	Number of Model-Predicted Exposures >120 dB Per Year
blue whale	112
fin whale	76
humpback whale	1,704
sei whale	562
sperm whale	1,747

Blue whale. The model output estimates that blue whales will be exposed to impulsive acoustic stressors from explosions associated with training activities throughout the year. The NAEMO provided an unprocessed estimate of 112 blue whale exposure events annually to impulsive sounds associated with annual training at levels above 120 dB SPL. Ninety-six (96) percent of the estimated 112 unprocessed exposures to blue whales during training activities will result from BOMBEX [A-S].

Fin whale. The model output estimates that fin whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 76 fin whale exposure events annually to impulsive sounds associated with annual training at levels above 120 dB SPL. Eighty-eight (88) percent of the estimated 76 unprocessed exposures to fin whales during training activities will result from BOMBEX [A-S].

Humpback whale. The model output estimates that humpback whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 1,704 humpback whale exposure events annually to impulsive sounds associated with annual training at levels above 120 dB SPL. Eighty-two (82) percent of the estimated 1,704 unprocessed exposures to humpback whales during training activities will result from BOMBEX [A-S].

Sei whale. The model output estimates that sei whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 562 sei whale exposure events annually to impulsive sounds associated with annual training at levels above 120 dB. Seventy-nine (79) percent of the estimated 562 unprocessed exposures to sei whales during training activities will result from BOMBEX [A-S]. Approximately 12 percent of exposures will result from GUNEX [S-S] Ship – Medium Caliber.

Sperm whale. The model output estimates that sperm whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of sperm 1,747 whale exposure events annually to impulsive sounds associated with annual training at levels above 120 dB. Fifty-two (52) percent of the estimated 1,747 unprocessed exposures to sperm whales during training activities will result from BOMBEX [A-S]. Approximately 21 percent of exposures will result from GUNEX [A-S] - Medium Caliber and 10 percent from GUNEX [S-S] Ship – Medium Caliber.

6.8.7.2 Processed Exposure to Impulsive Acoustic Stressors during Training Activities

There are limitations to the data used in the NAEMO, and the results must be interpreted with consideration for these known limitations. Output (Table 59 and Table 60) from the NAEMO relies heavily on the quality of both the input parameters and impact thresholds and criteria. When there was a lack of definitive data to support an aspect of the modeling (such as lack of well described diving behavior for all marine species), conservative assumptions believed to overestimate the number of exposures have been chosen:

- Marine mammals (virtual animals called “animats” in the model) are modeled as being underwater, facing the source and therefore always predicted to receive the maximum sound level at their position within the water column (e.g., the model does not account for conditions such as body shading, porpoising out of the water, or an animal raising its head above water). Some odontocetes have been shown to have directional hearing, with best hearing sensitivity facing a sound source and higher hearing thresholds for sounds propagating toward the rear or side of an animal (Kastelein et al. 2005; Mooney et al. 2008; Popov and Supin 2009).

- Animats do not move horizontally (but change their position vertically within the water column), which may overestimate physiological effects such as hearing loss, especially for slow moving or stationary sound sources in the model.
- Animats are stationary horizontally and therefore do not avoid the sound source, unlike in the wild where animals would most often avoid exposures at higher sound levels, especially those exposures that may result in PTS.
- Animats are assumed to receive the full impulse of the initial positive pressure wave due to an explosion, although the impulse-based thresholds (onset mortality and onset slight lung injury) assume an impulse delivery time adjusted for animal size and depth. Therefore, these impacts are overestimated at farther distances and increased depths.
- Multiple exposures within any 24-hour period are considered one continuous exposure for the purposes of calculating the temporary or permanent hearing loss, because there are not sufficient data to estimate a hearing recovery function for the time between exposures.
- Mitigation measures which are implemented during many training and testing activities were not considered in the model. In reality, sound-producing activities would be reduced, stopped, or delayed if marine mammals are detected within the mitigation zones around sound sources.

Observation of marine mammals prior to or during a detonation (explosion) would stop or delay the event until the area was cleared as described the Navy's Standard Operating Procedures, Mitigation, and Monitoring. This delay of the sound-producing activity (explosion) would reduce actual marine mammal sound exposures to zero at the level that rises to take pursuant to the ESA. Exposure to sound at lower levels may result in minor behavioral responses.

While there are model-predicted unprocessed exposures (Table 59 and Table 60) of cetaceans to impulsive sound sources (explosions), Navy post-calculations of these exposures reduced exposures to impulsive sources to zero. Therefore, any potential effects from impulsive sound sources on cetaceans are considered discountable.

6.8.7.3 Unprocessed Exposure to Impulsive Acoustic Stressors During Testing Activities

Navy model output estimates of cetaceans that will be exposed to impulsive acoustic stressors associated with testing activities throughout the year are summarized in Table 60 and discussed below.

Table 60. Model-Predicted, Unprocessed Exposures of Cetaceans to Impulsive Sound During Testing Activities

Species	Number of Model-Predicted Exposures >120 dB Per Year
blue whale	6
fin whale	7
humpback whale	213
sei whale	71
sperm whale	284

Blue whale. The model output estimates that blue whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of six blue whale exposure events annually to impulsive sounds associated with annual testing at levels above 120 dB. Sixty-nine (69) percent of the estimated 6 exposures to blue whales during testing activities will result from Anti-Submarine Warfare Tracking Test - Maritime Patrol Aircraft while 19 percent will result from Torpedo (Explosive) Testing and 11 percent from ASUW Mission Package Testing.

Fin whale. The model output estimates that fin whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of seven fin whale exposure events annually to impulsive sounds associated with annual testing at levels above 120 dB. Forty-five (45) percent of the estimated 7 exposures to fin whales during testing activities will result from Anti-Submarine Warfare Tracking Test - Maritime Patrol Aircraft while 31 percent will result from Torpedo (Explosive) Testing and 17 percent from ASUW Mission Package Testing.

Humpback whale. The model output estimates that humpback whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 213 humpback whale exposure events annually to impulsive sounds associated with annual testing at levels above 120 dB. Seventy-one (71) percent of the estimated 213 exposures to humpback whales during testing activities will result from Anti-Submarine Warfare Tracking Test - Maritime Patrol Aircraft while 16 percent will result from Torpedo (Explosive) Testing and 6 percent from ASUW Mission Package Testing.

Sei whale. The model output estimates that sei whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of 71 sei whale exposure events annually to impulsive sounds associated with annual testing at levels above 120 Db SPL. Seventy-seven (77) percent of the estimated 71 exposures to sei whales during testing activities will result from Anti-Submarine Warfare Tracking Test - Maritime Patrol Aircraft while 13 percent will result from Torpedo (Explosive) Testing and 8 percent from ASUW Mission Package Testing.

Sperm whale. The model output estimates that sperm whales will be exposed to impulsive acoustic stressors from explosions associated with testing activities throughout the year. The NAEMO provided an unprocessed estimate of sperm 284 whale exposure events annually to impulsive sounds associated with annual testing at levels above 120 dB SPL. Eighty-one (81) percent of the estimated 284 exposures to sperm whales during testing activities will result from Anti-Submarine Warfare Tracking Test - Maritime Patrol Aircraft while 7 percent will result from Torpedo (Explosive) Testing, 5 percent from MCM Mission Package Testing, and 4 percent from ASUW Mission Package Testing.

6.8.7.4 Processed Exposure to Impulsive Acoustic Stressors during Testing Activities

As discussed above for training activities, while there are model-predicted unprocessed exposures (Table 59 and Table 60) of cetaceans to impulsive sound sources (explosions), Navy

post-calculations of these exposures reduced exposures to impulsive sources to zero. Therefore, any potential effects from impulsive sound sources on cetaceans are considered discountable.

6.8.7.5 Response of Cetaceans to Impulsive Acoustic Stressors During Training and Testing

Since we do not anticipate exposures of cetaceans to impulsive acoustic stressors, we also do not anticipate any responses rising to the level of take. Therefore, we conclude that the potential for effects to cetaceans resulting from impulsive acoustic stressors is sufficiently low to be discountable and therefore is not discussed further in this Opinion.

6.8.8 Effects of Impulsive Acoustic Stressors - Sea Turtles

For this consultation, we considered exposure estimates from the Navy Acoustic Effects Model at several output points for sea turtles.

6.8.8.1 Unprocessed Exposures to Impulsive Acoustic Stressors During Training Activities

Unlike large cetaceans, observation of sea turtles prior to or during a detonation (explosion) is less effective and likely would not stop or delay the event until the area was cleared. Therefore, model-predicted exposures are used to derive potential levels of take for sea turtles although these takes will likely not be detected during training or testing. Navy model output estimates of sea turtles that will be exposed to impulsive acoustic stressors associated with training activities throughout the year are summarized in Table 61 and discussed below.

Table 61. Model-Predicted Unprocessed Exposures of Sea Turtles to Impulsive Sound During Training Activities

Species	Number of Model-Predicted Exposures >120 dB Per Year
Green Turtle	2,630
Hawksbill Turtle	210
Leatherback Turtle	67
Loggerhead Turtle	121

Green sea turtle. The NAEMO provided an unprocessed estimate of 2,360 green sea turtle exposure events annually to impulsive sounds associated with annual training activities at levels greater than 120 dB SPL. Thirty-two (32) percent of the estimated 2,630 green sea turtle exposures will result from BOMBEX [A-S] while 26 percent will result from Underwater Demolition Qualification / Certification, 17 percent from Mine Neutralization – EOD and 11 percent Maritime Security Operations.

Hawksbill sea turtle. The NAEMO provided an unprocessed estimate of 210 hawksbill sea turtle exposure events annually to impulsive sounds associated with annual training activities at levels greater than 120 dB SPL. Forty-five (45) percent of the estimated 210 hawksbill sea turtle exposures will result from BOMBEX [A-S] while 19 percent will result from Underwater Demolition Qualification / Certification, 13 percent from Mine Neutralization – EOD.

Leatherback sea turtle. The NAEMO provided an unprocessed estimate of 67 leatherback sea turtle exposure events annually to impulsive sounds associated with annual training activities at

levels greater than 120 dB SPL. Eighty-five (85) percent of the estimated 67 leatherback sea turtle exposures will result from BOMBEX [A-S] while 7 percent will result from GUNEX [S-S] Ship – Medium Caliber.

Loggerhead sea turtle. The NAEMO provided an unprocessed estimate of 121 loggerhead sea turtle exposure events annually to impulsive sounds associated with annual training activities at levels greater than 120 dB SPL. Fifty-six (56) percent of the estimated 121 loggerhead sea turtle exposures will result from BOMBEX [A-S] while 28 percent will result from GUNEX [S-S] Ship – Medium Caliber.

6.8.8.2 Unprocessed Exposures to Impulsive Acoustic Stressors During Testing Activities

Navy model output estimates of sea turtes that will be exposed to impulsive acoustic stressors associated with testing activities throughout the year are summarized in Table 62 and discussed below.

Table 62. Model-Predicted Exposures of Sea Turtles to Impulsive Sound During Testing Activities

Species	Number of Model-Predicted Exposures >120 dB Per Year
Green Turtle	489
Hawksbill Turtle	52
Leatherback Turtle	29
Loggerhead Turtle	32

6.8.8.3 Processed Exposures to Impulsive Acoustic Stressors During Training and Testing

Navy modeling (Table 63) results indicate 14 TTS-level exposures, 1 PTS-level exposure, 4 exposures resulting in slight lung injury, and 2 exposures resulting in mortality combined for green and hawksbill turtles. No TTS, PTS, injury or mortality was predicted by the NAEMO modeling for loggerheads, or leatherback turtles.

Table 63. Annual Model-Predicted Impacts on Sea Turtles from Explosives Used During Training and Testing Activities

Sea Turtle Species	TTS	PTS	GI Tract Injury	Slight Lung Injury	Mortality
Green sea turtle	**11**	**1**	0	**3**	**1**
Hawksbill sea turtle	**3**	0	0	**1**	**1**
Loggerhead sea turtle	0	0	0	0	0
Leatherback sea turtle	0	0	0	0	0

6.8.8.4 Estimated Instances of Behavioral Harrassment of Sea Turtles from Impulsive Acoustic Stressors

In addition to Navy-modeled estimates for TTS, PTS, Slight Lung Injury, and Mortality from impulsive acoustic stressors, we calculated the number of modeled (unprocessed) instances of behavioral harassment of sea turtle species. To do this, we summed the number of modeled

exposures greater than 175dB (See Section 6.3.6) and subtracted instances of estimated TTS, PTS, slight lung injury, and mortality to provide an estimate (balance of exposures greater than 175dB) of exposures that may result in more than minor behavioral responses potentially rising to the level of "take" pursuant to the ESA. These unprocessed estimates do not take into account U.S. Navy standard operating procedures and mitigation activities that might reduce actual instances of harassment. We also acknowledge that individuals experiencing TTS, PTS, or slight lung injury likely also experience some form of behavioral response associated with these responses; however, we do not double count these instances to remain consistent with our analysis of TTS, PTS, injury where only the highest level response is counted towards take.

Table 64. Annual Estimated Behavioral Harrassment of Sea Turtles from Training and Testing Activities Using Impulsive Acoustic Sources

Sea Turtle Species	Behavioral Harrassment
Green sea turtle	1,837
Hawksbill sea turtle	129
Leatherback sea turtle	49
Loggerhead sea turtle	54

6.8.8.5 Response of Sea Turtles to Impulsive Acoustic Stressors During Training and Testing

Most detonations would typically occur beyond approximately 12 nm from shore, which minimizes the impacts near nesting beaches or coastal habitats for sea turtles. Any injured sea turtles could suffer reduced fitness and long-term survival. As also discussed in Section 6.8.4.4, sea turtles that experience PTS would have permanently reduced perception of sound within a limited frequency range. It is uncertain whether some permanent hearing loss over a part of a sea turtle's hearing range would have long-term consequences for that individual, as the sea turtle hearing range is already limited. A long-term consequence could be an impact on an individual turtle's ability to sense biologically important sounds, such as predators or prey, reducing that animal's fitness. PTS and TTS threshold criteria for sea turtles are conservatively based on criteria developed for mid-frequency marine mammals, so actual PTS and TTS impacts may be less than the predicted quantities.

Some sea turtles beyond the ranges of the TTS or PTS-level effects may behaviorally react if they hear a detonation. If a sea turtle hears multiple detonations in a short period, such as during gunnery, firing, or sonobuoy exercises, it may react by temporarily avoiding the area. Any significant behavioral reactions could lead to a sea turtle expending energy and missing opportunities to feed, nest or rest. However, because most activities would consist of a limited number of detonations and exposures would not occur over long durations, there would be an opportunity to recover from an incurred energetic cost.

Most impacts would be short-term, potential impacts are not expected to result in substantial changes to behavior, growth, survival, annual reproductive success, lifetime reproductive success (fitness), or species recruitment. Although a few individuals may experience long-term impacts and potential mortality, population-level impacts are not expected.

Although we assume that sea turtles in the vicinity of an in-water detonation might experience a TTS or PTS, it is not certain at what energy levels and received levels are necessary to induce threshold shifts. The few studies completed on the auditory capabilities of sea turtles (adult green, loggerhead, and Kemp's ridley turtles) suggest that they could be capable of hearing low frequency sounds (Lenhardt 1994a; Moein et al. 1993; Ridgway et al. 1969). Ridgway et al. (Ridgway et al. 1969) reported maximal sensitivity for green turtles occurred at 300 to 400 Hz, with a rapid decline in sensitivity for lower and higher tones. Similarly, Moein et al. (Moein et al. 1993) reported a hearing range of about 250 to 1,000 Hz for loggerhead turtles, and Lenhardt (Lenhardt 1994a) stated that maximal sensitivity in sea turtles generally occurs in the range from 100 to 800 Hz. Calculated in-water hearing thresholds within the useful range appear to be high (e.g., about 160 to 200 dB re 1 μPa) (Lenhardt 1994a). Piniak et al. reported maximum sensitivity between 100 and 400 Hz in water (84 dB re: 1 μPa at 300 Hz) and 50 and 400 Hz in air (62 dB re: 20 μPa at 300 Hz) for leatherback sea turtle hatchlings (Piniak et al. 2012). In the absence of more specific information that could be used to determine the acoustic harassment range for sea turtles, the U.S. Navy assumed that frequencies >100 Hz (which are the acoustical harassment ranges predicted for odontocetes) would be conservative for sea turtles. Given that sea turtles do not rely on acoustic cues for most important life functions, it is anticipated that TTS and PTS will not result in fitness consequences to individuals or the populations to which they belong.

Acoustic stressors associated with the Navy's activities in the MITT Action Area have the ability to cause slight lung injury. Slight lung injury is defined as having a zero percent mortality rate and being completely recoverable. Although slight lung injuries could temporarily affect the fitness of affected individuals by reducing their respiration rate, these effects are expected to stop once the injury has healed. Because sea turtles are long-lived animals, a temporary disruption of behaviors or fitness levels resulting from slight lung injury is not expected to substantially impair an individual turtle when considering its overall lifetime fitness. Because we do not expect fitness consequences to any individuals, we do not expect population-level consequences.

Impulsive acoustic stressors from Navy training and testing activities conducted annually and continuing into the reasonably foreseeable future are likely to cause behavioral responses, and instances of TTS, PTS, slight lung injury, and mortality to sea turtles in the MITT Action Area. There is no evidence that behavioral responses, TTS, or PTS result in energetic effects to individual sea turtles or would be likely to significantly reduce the viability of the population these individuals represent. While we anticipate small numbers (See Table Table 63) of injury and mortality of green and hawksbill sea turtles from impulsive acoustic stressors in the MITT Action Area that would have fitness consequences on individual sea turtles, we do not anticipate those levels of injury and mortality to result in substantial changes in reproduction, numbers, or distribution of green or hawksbill sea turtle populations.

6.8.9 Effects of Impulsive Acoustic Stressors - Scalloped Hammerhead Shark – Indo-West Pacific DPS

The following section discusses the effects of impulsive acoustic stressors on scalloped hammerhead sharks.

6.8.9.1 Exposure to Impulsive Acoustic Stressors During Training

Agat Bay Mine Neutralization Site and Outer Apra Harbor UNDET (Figure 5) will support activities using explosives up to 20 lb. and 10 lb. NEW devices, respectively. Explosives used at the Piti Floating Mine Neutralization Site are also limited to 10 lb. NEW. In total, approximately 260 explosives would be used annually in shallow water and coastal areas (e.g., Apra Harbor, Agat Bay, Piti Point) per year (Figure 5). The scalloped hammerhead shark is primarily a shallow water, coastal species. Underwater detonations will primarily occur during the day when this species is more likely to be closer to shore. Additionally, Navy divers involved with underwater detonation in the at these sites will visually observe to the best extent practicable for hammerhead sharks prior to initiating detonation as part of the diver's normal underwater training procedures. If hammerhead sharks are observed within the immediate area, then detonation will be delayed until the shark is no longer observed in the immediate area.

The density of scalloped hammerhead sharks in the shallow, nearshore waters of the Action Area are not well understood but anecdotal evidence suggests inner Apra Harbor may serve as nursery habitat for this species (Miller et al. 2014). If Apra Harbor acts as a nursery for this species, juveniles may seasonally occur in substantial densities and it can also be reasonably expected adult males and females would frequently move between Apra Harbor and nearshore areas outside the harbor. One of the underwater detonations sites is within Apra Harbor itself, Agat Bay is south of Apra Harbor, and the Piti site is immediately north of Apra Harbor.

Although sound thresholds capable of inducing behavioral responses and injury in scalloped hammerhead sharks have not been determined, it is expected they will be less susceptible than marine mammals and fish species with swim bladders. Using the formula Young (1991) for effects of underwater detonations to fish without a swim bladder, it is estimated 90 percent of scalloped hammerhead sharks would likely survive at a range of 2.2 meters (7.3 feet) or further from a 10 lb. NEW explosive underwater detonation and 2.8 meters (9.2 feet) or further from a 20 lb. NEW underwater detonation. Therefore, the mortality zone for a 10 lb. NEW charge would be approximately 15.21 m^2 (167.42 ft^2) and approximately 24.63 m^2 (267 ft^2) for a 20 lb. NEW charge. Navy divers observe the underwater detonation site prior to detonation, which should minimize the likelihood of detonating explosives while scalloped hammerhead sharks (or other ESA-listed species) are within the immediate vicinity, thereby minimizing injury or mortality. Since scalloped hammerhead sharks may occur at all three sites, and we do not have the breakdown of planned detonations at the three sites by NEW, we will assume a worst case scenario with all 260 planned detonations using 20 lb. NEW. We assume that mitigation measures including detection of scalloped hammerhead sharks (or any shark species) within the underwater detonation site exclusion zones prior to detonation and subsequent delay of detonation until the area is clear would effectively eliminate the potential for direct injury or mortality resulting from exposure of scalloped hammerhead sharks within 2.8 meters (9.2 feet) of a 20 lb. charge detonation.

While we do not expect detonations to result in any instances of shark mortality, sub-lethal effects (temporary hearing loss, behavioral response) could occur. Due to a lack of shark density information and hearing/behavioral threshold data, it is not feasible to estimate the number of scalloped hammerhead sharks exposed to sublethal effects from impulsive acoustic stressors associated with underwater detonations. Since estimating the number of individual exposed

scalloped hammerhead sharks is not feasible, we use the amount of affected habitat as a surrogate to analyze the effects of impulsive acoustic stressors on the Indo-West Pacific DPS of scalloped hammerhead shark.

In the absence of information on range to significant behavioral effects to scalloped hammerhead sharks from underwater detonations and lack of data on the efficacy of Navy mitigation including the ability to detect scalloped hammerhead sharks during routine underwater detonation activities, we doubled the estimated mortality zones for 20 lb. NEW detonations to derive an area (displacement zone) where scalloped hammerhead sharks might experience behavioral responses, TTS, temporary disruption of feeding, breeding, or sheltering activities, or the reduced availability of preferred habitat. We determined that the affected habitat area for a 20 lb. NEW charge would be 99 m2 (1,064 ft^2) per detonation (based on a radius of impact of 5.6m). While we did not exclude the estimated mortality zone from this larger displacement area, we still assume the injury and mortality is not likely. We anticipate that up to 260 charges would be detonated annually at underwater detonation sites where scalloped hammerhead sharks may be present. In this scenario, any scalloped hammerhead sharks within the 99 m^2 area would be behaviorally-harassed, or up to 99 m^2 of their habitat would be temporarily displaced during each detonation. We expect the 260 underwater detonations and subsequent effects to be distributed across the Piti Point, Outer Apra Harbor, and Agat Bay sites throughout a given year, and we anticipate the number of charges that are routinely detonated in a day (no more than five) or week (no more than 20) would result in temporary effects that would not lead to a significant reduction in feeding, breeding, or sheltering opportunities. That is, we expect normal behavioral activities of scalloped hammerhead sharks and the availability of this habitat to sharks to resume soon after each of the 260 disturbances events have concluded.

Based on the ETOPO1 Global Relief Model Bathymetry data available from NOAA's National Geophysical Data Center there are approximately 19,462,434 km^2 of ocean with depths less than 1,000 m (where scalloped hammerhead sharks are most likely to occur) occurring within listed DPS segments. The Indo-West Pacific DPS contains 13,510,249 km^2 of ocean with depths less than 1,000 m (Figure 26).

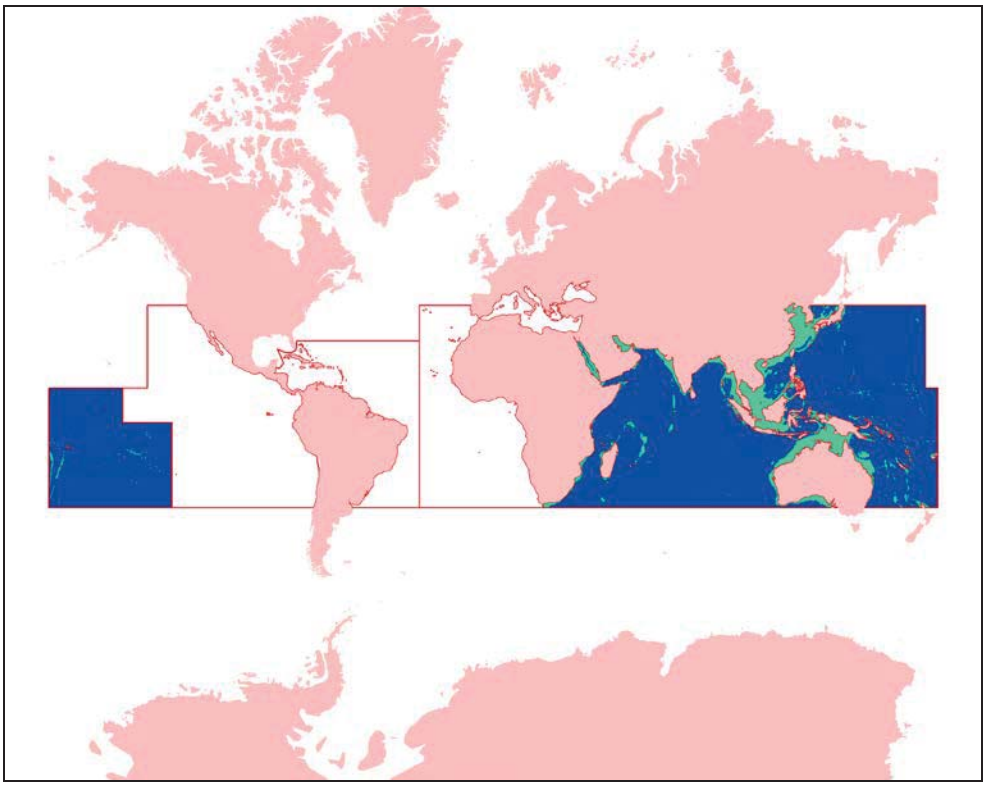

Figure 26. The Indo-West Pacifc DPS of scalloped hammerhead sharks. Dark blue areas are waters with depths greater than 1,000 m while light blue areas are waters with depths less than 1,000 m. The total area of water with depths less than 1,000 m is 13,510,249 km^2.

6.8.9.2 Exposure to Impulsive Acoustic Stressors During Testing

No MITT testing activities include underwater detonations at the Apra Harbor, Agat Bay, or Piti Point sites. The use of impulsive airguns for pierside integrated swimmer defense testing activities occurring in Inner Apra Harbor will occur infrequently (no more than 11 activities totaling 308 hours per year) and will occur in a high-use area with high ambient noise levels. The small airguns used in pierside testing activities lack the strong shockwave and pressure increases associated with underwater detonations. These airguns produce 185 to 195 dB re 1 µPa^2 SEL at 1 m. The small ensonified area capable of eliciting an injury or behavioral response of scalloped hammerhead sharks and the limited duration of impulsive acoustic energy from swimmer defense airguns indicate the likelihood of exposure of scalloped hammerhead sharks to impulsive acoustic energy resulting in take from pierside integrated swimmer defense testing activities to be so low as to be discountable. Therefore, no exposure of scalloped hammerhead sharks to impulsive acoustic stressors during testing is anticipated.

6.8.9.3 Response to Impulsive Acoustic Stressors During Training and Testing

Given the short distance from the detonation source that a shark would need to be for injury or mortality to occur and the mitigation procedures for underwater detonations, it is unlikely that scalloped hammerhead sharks would be injured or killed during underwater detonations. However, scalloped hammerhead sharks may experience hearing loss if within an unknown

distance to the underwater detonation. Hearing loss would be temporary because unlike marine mammals, fish are capable of regenerating sensory hair cells and no permanent hearing loss has ever been reported in fish (Lombarte et al. 1993) (Smith et al. 2006b).

Additionally, the potential for behavioral harassment remains. As discussed above, we were unable to quantify the number of individual scalloped hammerhead sharks that could experience behavioral harassment. Instead, we estimated the area of affected habitat as a surrogate to define take. Because scalloped hammerheads are long-lived, highly mobile animals and alternate habitat is available outside of the habitat area expected to be effected during each underwater detonation event, sharks that are temporarily displaced from their preferred habitat would likely select adjacent habitat where forage, breeding habitat and refugia is available. Also, instances of temporary hearing loss are not expected to substantially impair individual scalloped hammerheads when considering overall lifetime fitness. We do not anticipate any responses of scalloped hammerhead sharks to integrated swimmer defense testing activities that would rise to the level of take. Because we do not expect fitness consequences to any individuals resulting from temporary displacement of habitat or TTS, we do not expect population-level consequences.

6.8.10 Effects of Impulsive Acoustic Stressors and Military Expended Materials

The effects of impulsive acoustic stressors on marine mammals, sea turtles, and scalloped hammerhead sharks are discussed in sections 6.8.7, 6.8.8, and 6.8.9, respectively. The effects of military expended materials on these species are discussed below in Section 6.8.10.1. In Section 6.8.10.2, we combined the discussion of the effects of impulsive acoustic stressors and military expended materials on *Acropora globiceps* because both stressors are related to the use of ordnance.

6.8.10.1 Marine mammals, sea turtles, and scalloped hammerhead sharks

Military expended materials include all sizes of non-explosive practice munitions, fragments from explosive munitions, and expended materials such as sonobuoys, ship hulks, and targets. The expected density of ESA-listed marine mammals, sea turtles, and scalloped hammerhead sharks in areas receiving a majority of munition, and ordnance testing that could potentially strike these species is very low. The impact site for munitions, dropped ordnance, and other expended materials have very small footprints. The density of marine mammals, sea turtles, and scalloped hammerhead sharks; the small footprint of expended materials; and the Navy's strike modeling efforts suggest direct strikes to these species from expended materials is so unlikely as to be discountable. According to the Navy's BE, there are no records of military expended materials striking marine mammals, sea turtles, or scalloped hammer head sharks further supporting this conclusion.

6.8.10.2 Acropora globiceps

The following sections discuss the effects of impulsive acoustic stressors on colonies of *Acropora globiceps*. The available information regarding the distribution of *Acropora retusa* and *Seriatopora aculeata*, does not suggest these species are likely to occur near underwater detonation sites or at-sea target sites. Therefore, we only analyze effects to *Acropora globiceps* in this section.

Little is known about the long-term ecosystem effects of blast impacts or the dynamics of recovery of corals from underwater or surface detonations within close proximity of corals. With regard to the use of military ordnance at FDM, we would expect areas to receive periodic disturbance from military expended materials impacting reefs and sporadic detonations near the surface in relatively shallow waters. In fewer instances, ordnance may impact at or near the bottom or directly on coral reefs.

Direct trauma and mortality may occur due to the rapid pressure changes associated with an explosion. Though most invertebrates lack air cavities that would respond to pressure waves, which typically causes the most damage in fish or marine mammals, a blast in the vicinity of hard corals (i.e., *Acropora globiceps*) could cause direct impact to coral polyps, or fragmentation and siltation of the corals. A blast near the bottom could also disturb hard substrate suitable for colonization.

The effects of dynamite or "blast" fishing may help provide some insight to the potential effects of detonation of live military ordnance in and around coral colonies. However, it is worth noting that blast fishing detonations typically occur at depth (i.e., near or on the substrate) (Fox and Caldwell 2006), whereas the military detonations that may occur near FDM would be expected to occur at the surface of the water. The shock waves from blast fishing explosions break the coral's calcium carbonate skeleton into small pieces. Once broken, the coral/algal symbiotic relationship is disrupted and the coral begins to lose nourishment and starts to die.

Coral reef survival and recovery may be affected by acute single blasts as well as chronic blasting over greater spatial and temporal scales. Fox and Caldwell (2006) examined coral reef recovery following acute single blasts and following chronic blasting. Rubble resulting from single blasts slowly stabilized, and craters filled in with surrounding coral and new colonies. After five years, coral cover within craters formed by single blasts no longer differed significantly from control plots. In contrast, extensively bombed areas showed no significant recovery over the six years of the study, despite adequate supply of coral larvae. After extensive blasting, resulting coral rubble may shift in ocean currents, abrading or burying new coral larvae, thereby slowing reef recovery (Fox and Caldwell 2006). McManus (1997) suggested that blastfishing in Bolinao, Philippines may reduce the growth capacity of scleractinian coral on the reef slope by approximately one third.

A study at a former U.S. Navy range at Vieques Island (Puerto Rico, United States), which is now the largest national wildlife refuge in the Caribbean, investigated the geomorphology and benthic assemblage structure to understand the status of the coral reefs. In that study (Reigl et al. 2008), investigators found no differences in living benthic coral reef cover or composition of coral assemblages inside and outside the bombing range or in comparison to reefs investigated on St. Croix. Reigl et al. (2008) concluded that this may indicate not that zero impacts occurred but rather that natural disturbances appear to have altered the coral communities drastically, thus obscuring military impacts. Effects of natural disturbances were severe at Vieques, outweighing impacts of past military activity which were present but not quantitatively discernible at the scale of sampling. Disease and storms, rather than military expended ordnance, were seen to have taken the worst toll on corals at both Vieques and St. Croix (Reigl et al. 2008).

The US Navy conducted annual nearshore marine resource surveys around FDM from 1999 through 2012 (except 2011). A 2013 report presented the findings of the calender year 2012 survey and compares findings from those of the previous 12 surveys (Smith et al. 2013). The report indicates that despite ongoing use by the Department of Defense as a live and inert range, no significant impacts to the physical or biological environment were detected between 1999 and 2012. Direct ordnance impacts upon the submerged physical environment, which were clearly attributable to training activities, were detected in 2007, 2008, 2010, and 2012. Indirect impacts, such as ordnance that skipped or eroded off the island and rock and ordnance fragments blasted off the island were detected every year. The report indicated that very few areas of disturbance were detected, the size of any disturbed areas were generally less than 2 m^2, and substantial or complete recovery of these disturbed areas occurred within one year. Additionally, large numbers of one and two year old stony coral recruits were consistently observed, suggesting that coral recruitment is not a limiting factor around the island. The report also indicated that restricted access to FDM (because it is a DoD live and inert range) may have a conservation benefit to the reef ecosystem around the island, with marine resources at FDM comparable to or superior to those of any of the other islands within the Mariana Archipelago (Smith et al. 2013).

6.8.10.2.1 Exposure of Corals to Impulsive Acoustic Stressors Around Guam

The vast majority of training and testing activities around Guam that use explosives occur in areas greater than 12 nm from shore and thus not considered further in this Opinion. The Agat Bay Mine Neutralization Site is located beyond 3 nm of Guam and is capable of supporting activities using explosives up to 20 lbs. NEW, but this site is located in water depths deeper than eight meters (maximum known depth of *Acropora globiceps*). Explosives used at the Piti Point Mine Neutralization site and Outer Apra Harbor UNDET sites are limited to 10 lbs. NEW. Of these sites, the Outer Apra Harbor UNDET site and Piti Point Mine Neutralization site are within less than one kilometer of existing reef structures known to support coral growth (Figure 27).

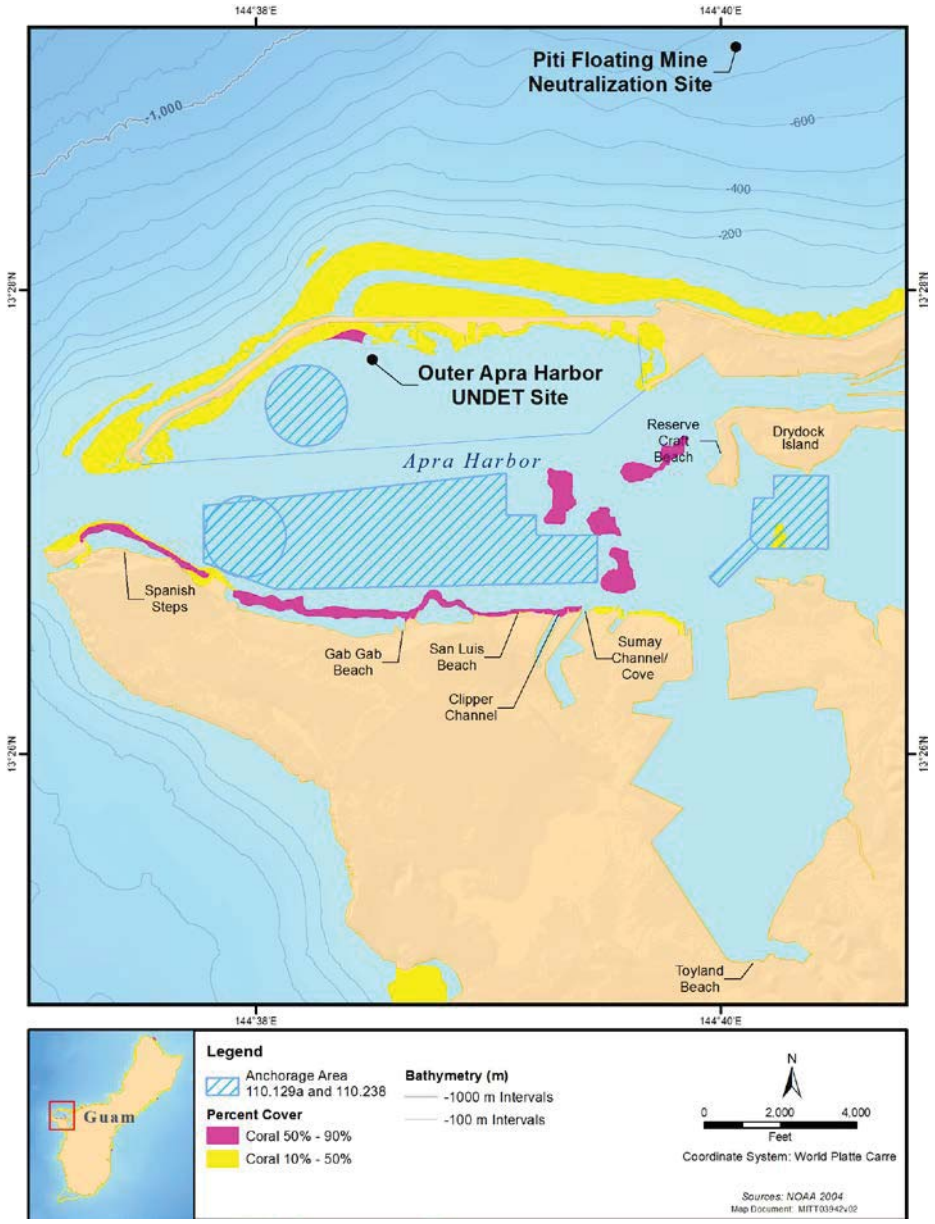

Figure 27. Underwater Detonation and Mine Neutralizaton Sites in and around Apra Harbor, Guam

Effects from explosions at these locations are not reasonably expected to affect ESA-listed coral colonies due to the distance between UNDET and mine neutralization sites, and known locations of *Acropora globiceps,* as well as precautions taken by the Navy during mine neutralization activities. Several surveys have been conducted within Apra Harbor (e.g., (Smith et al. 2009), (Starmer 2008)) and in only two instances (Schils et al. 2011), TetraTech 2015), was *Acropora globiceps* observed. However, the species was observed near Kilo Wharf and Spanish Steps, located across Apra Harbor from the UNDET site. The species has not been documented within a close enough to the Outer Apra Harbor UNDET site to be adversely effected by Navy activities at this site. It is possible that *Acropora globiceps* is present at the Piti Point UNDET site, most

likely very close to shore. However, no more than a 10 lb NEW detonation will be used at this site, resulting in a percussive effect of about 10 feet. All UNDET locations are monitored for presence of corals and the Navy maintains a distance of 350 feet from hard bottom structures (e.g., coral reefs) during detonations, indicating that coral reefs (including those that may contain *Acropora globiceps*) are not expected to be affected. For these reasons, *Acropora globiceps* adult colonies are not expected to be affected by detonations around Guam.

6.8.10.2.2 Exposure of Corals to Impulsive Acoustic Stressors Around Farallon de Medinilla

In 2004, 81 species of corals, including *Acropora globiceps,* were observed on reefs at FDM (DoN 2005b) where training or testing activities using explosives would occur. *Acropora retusa* and *Seriatopora aculeata* have also been documented in either Guam or CNMI, respectively. However, the available information does not suggest these species are likely to occur in the reefs around the island (D. Fenner, personal communication, May 13, 2015). Therefore, *Acropora globiceps* could be impacted by explosion of live ordnance that miss or skip off intended onshore targets at FDM and land in the adjacent nearshore environment and either detonate upon impact with the water at or near the surface or do not detonate and sink to the bottom either impacting substrate or potentially coral colonies in the area. FDM has a relatively wide insular shelf (400 to 1,800 m wide) that supports limited coral cover along all sides except portions of the western side of the island (Figure 28).

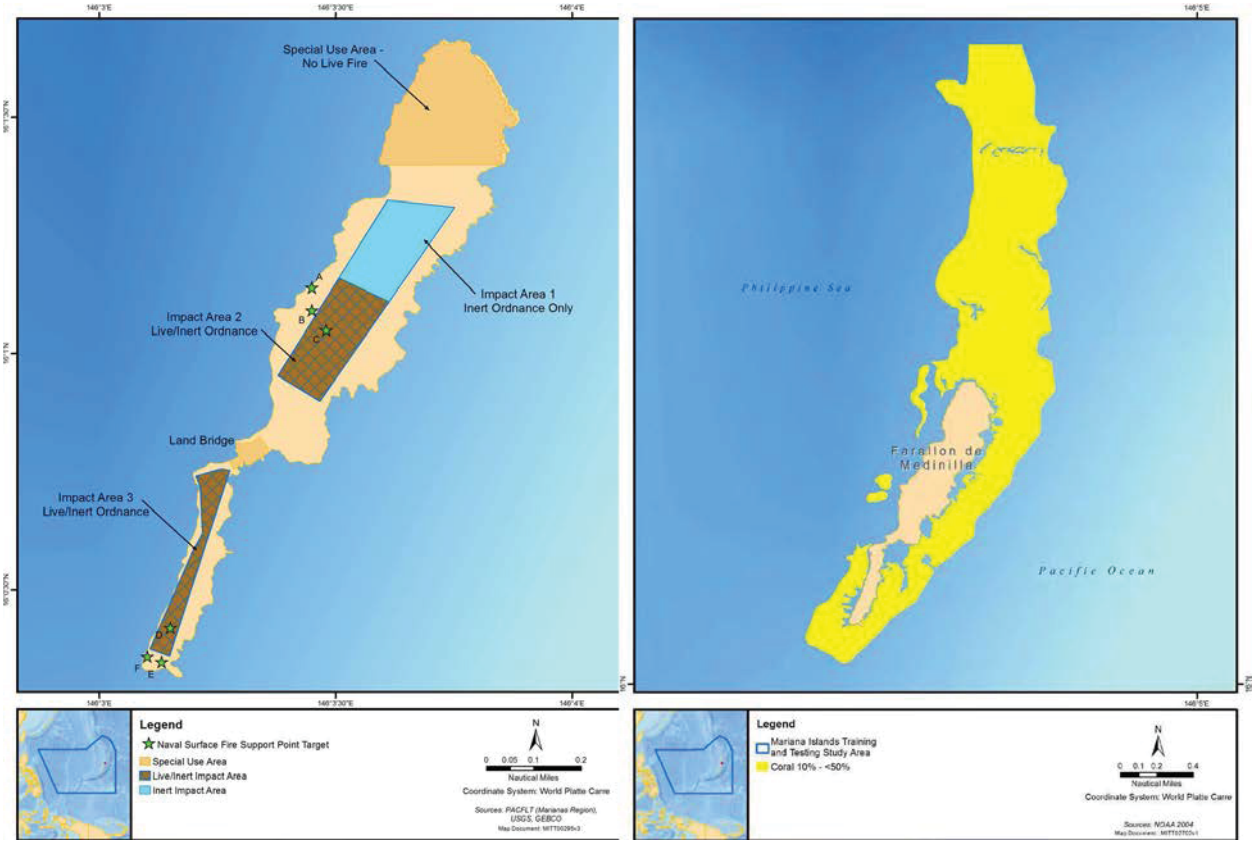

Figure 28. Coral reef structures (right picture highlighted in yellow) in relation to impact areas on Farallon de Medinilla. Reef structures within approximately 0.5 km of the shoreline cover an area of approximately 1.7 km^2.

Near the cliff edge on the reef terrace of the eastern side of FDM, there is estimated to be less than 5 percent coral cover (DoN 2005b). Further offshore, there is estimated to be 10 to 20 percent coral cover composed of encrusting *Porites* and head coral forming *Pocillopora*. Coral cover on the boulders is estimated to be 25 to 30 percent and comprised primarily of *Pocillopora*, *Porites*, *Montipora*, and *Millepora*. Coral cover on the ridges of the spur-and-groove system off the island isthmus on the windward side ranges is estimated to be from 15 to 25 percent, and is composed of *Porites* and *Pocillopora*.

As described above in Section 0, FDM has been a target site for live-fire military exercises (ship-to-shore gunfire, aerial gunnery and bombing) since 1971 (Smith et al. 2013). While the majority of live and inert ordnance strikes the island and does not impact the nearshore marine environment, there are known instances where bombs have missed the island or rolled down into the water after impact.

In order to estimate the incidences of injury or mortality to ESA-listed corals around FDM that result from direct strike of ordnance, in-water explosions of ordnance, and direct strike of corals from fragments of exploded or inert ordnance richocheting from land-based targets, we performed the following analysis:

Step One. Determine Relative Abundance of *Acropora globiceps*

Survey data (DoN 2005b) indicate that *Acropora globiceps* is the only ESA-listed coral that is likely to inhabit waters around FDM. We assumed that all of the coral reefs round FDM would be populated with patchy but fairly uniform distributions of coral colonies including *Acropora globiceps.* Near the cliff edge on the reef terrace of the eastern side of FDM, there is estimated to be less than 5 percent coral cover (DoN 2005b). Further offshore, there is estimated to be 10 to 20 percent coral cover. Coral cover on the boulders is estimated to be 25 to 30 percent. Coral cover on the ridges of the spur-and-groove system off the island isthmus on the windward side ranges is estimated to be from 15 to 25 percent (DoN 2005b). Based on these values, we estimate an average coral coverage of approximately 18.6 percent around FDM.

Survey data from FDM indicate that the relative abundance of *Acropora globiceps* compared to the other 80 species identified in the area is rare (DoN 2005b). We compared 260 records of observed species from six different survey transects and attributed a number of colonies to each based on the relative abundance of each record (abundant = 25 colonies, common = 20 colonies, occasional = 10 colonies, and rare = 5 colonies; as defined in the DoN (2005) report (Table 65). For example, in survey D1, three species were identified as abundant, meaning the surveyors observed 25 or more colonies of each of those species. Surveyors identified 14 rare species in transect D1, meaning that these 14 species were observed five or fewer times on the survey. *Acropora globiceps* was observed during two of the surveys, and was not observed more than five times during those surveys. Therefore, for the purpose of calculating the relative abundance

of *Acropora globiceps*, we assumed a maximum of 10 total colonies were observed during six transects. The six survey transects resulted in the estimation of 2,270 colonies of all 81 species around FDM. Therefore, the proportion of *A globiceps* to all coral species observed around FDM is 0.0044 (10 *Acropora globiceps* colonies/2,270 total coral colonies = 0.0044).

Table 65. Survey data used to calculate the relative abundance of *Acropora globiceps* in coral habitat around FDM. Survey data was from (DoN 2005b).

Relative Abundance	Transect						Total Records	Colonies per Record	Total Colonies
	D1	D2	D3	D4	D5	D6			
Abundant	3	3	5	3	1	1	16	25	400
Common	4	3	5	3	1	5	21	20	420
Occasional	16	11	12	7	10	11	67	10	670
Rare	14	25	33	22	24	38	156	5	780
Total	37	42	55	35	36	55	260	-	2270

Step Two. Determine *Acropora globiceps* colony size in reference to reef area surrogate

The Final Rule regarding Incidental Take Statements (80 FR 26832) allows the use of surrogates in determining the level of expempted take for ESA-listed species when take of individual listed species is not readily observable. However, to understand the observed or estimated incremental effects of an action on a surrogate, we must understand the causal link between the surrogate and the take of the species (section 6.5 describes how we delineate an individual coral). *Acropora globiceps* in the CNMI have been observed to be roughly 10 to 20 cm in diameter (D. Fenner, personal communication, May 14, 2015). Using an average of 15 cm diameter, **the average colony area is 0.01767 m^2**.

Step Three. Estimate the number of live and inert munitions that impact coral habitat

FDM supports a full suite of munitions use, from the delivery of heavyweight explosive bombs dropped from fighter aircraft to small arms fire from helicopters. Up to 6,242 explosive bombs and 2,670 non-explosive bombs would be expended annually at FDM (8,912 total). Bombs range in size from 25 pounds to 2,000 pounds. Up to 42,000 small-caliber projectiles would be expended annually at FDM. Small-caliber projectiles are those projectiles that are 50 caliber and below. Small caliber projectiles will lose most of their energy upon contact with the water surface and are not expected to impact *Acropora globiceps* with enough force to cause a measurable effect. Up to 17,350 explosive and 94,150 non-explosive projectiles would be expended annually. Medium caliber projectiles are those projectiles that are greater than 50 caliber, but less than 57mm. Up to 1,200 explosive, large-caliber projectiles and up to 1,800 non-explosive large-caliber projectiles would be expended annually. Large caliber includes 5 inch ship fired projectiles as well as mortars fired into the impact areas from the northern end of FDM. Up to 85 explosive missiles would be expended and up to 2,000 explosive rockets would be expended annually at FDM. Table 66 provides estimates of the annually-expended ordnance that is anticipated to miss or richochet off of the on-land target impact areas and land in

nearshore waters. Further detail regarding the estimation of total reef area impacted by munitions at FDM is available in a memo to the file (Environmental Readiness Division (N465) 2015). This memo includes information on how the Navy estimated the percent of items that fall in the water and the percent of those items that are assumed to impact coral habitat.

Table 66. Estimated Area of Coral Habitat Impacted by Ordnance at Farrallon de Medinilla

Ordnance Items per the Proposed Action (FEIS/OEIS)	Number of Items Expended Annually	Percent of Items That Fall in Water	Number of Items That Fall in Water	Percent of Items Assumed to Impact Reefs	Number of Items Assumed to Impact Reefs	Impact Area Per Item (m2)	Total Coral Habitat Area (m2)
Bombs (HE)[1]	6,242	1	62.42	100	62.42	132.73	**8,285.0066**
Bombs (NEPM)	2,670	2	53.4	100	53.4	3.0044	160.43496
Bomb debris (end plates)	6,242	50	3,121	17	530.57	0.072929	38.693879
Bomb Debris (ejecta)	6,242	50	3,121	17	530.57	0.072929	38.693879
Small-caliber projectiles	42,000	5	2,100	17	357	0.0056	1.9992

						Total Habitat Area Affected	**8,547.1552**

[1] Bombs (HE) is the only ordnance anticipated to result in mortality of coral colonies

For bombs with high explosives (HE) that may have greater impacts (see footnote in table), we also assessed the potential mortality and injury zones from a documented Navy observation of an underwater impact crater.

Step Four. Determine the Range to Effects for Injury and Mortality from Detonations of Bombs (HE)

During a 2010 survey, a fresh shallow crater was observed for the first time since 1999. It was located in the southern portion of Z3W. The crater pit was 5 m across in its maximum dimension and the cratered portion of the seafloor was a maximum of 50 cm deeper than the surrounding sea floor. Water depth at the site was 12 m. Explosive Ordnance Disposal (EOD) Detachment "MARI" personnel judged that a bomb had detonated at the water surface to produce the disturbance. This event occurred in an area that was dominated by relatively barren bedrock. No

corals or any other sessile benthic invertebrates or the remains thereof were observed in the crater/blast pit or within a distance of approximately 4 m from the edge of the crater. Past the 4 m perimeter, (approximately 9 m from the center of the impact site) sea floor cover by corals was estimated to be less than 5 percent. The bedrock segments of the sea floor with less than 5 percent coral cover are 'natural' around much of FDM at depths of 14 m or less. Note, this low percentage of sea floor cover by coral was uniform for most of Z3W, except on the tops of some large cliff blocks and boulders where coral cover ranged up to 50 percent and the SW portion of Z3W where extensive coral development occurs with coverage > 50 percent (Navy, pers. comm., memorandum to the record, May 8, 2015).

This observation suggests that any coral within a circular area with a diameter of 13 meters (5m + 4m + 4m) could have been impacted, as coral beyond this range appear to be similar to undisturbed background locations. From this observation, we established a mortality zone extending 6.5 meters from the center of the crater, equating to an area of 132.73 m^2. To estimate potential injuries outside of the mortality zone, and in the absence of any available information on distance to effects for explosions and corals, we assumed that recoverable injuries (e.g., breakage) might occur within a zone extending another 6.5 meters past the mortality zone (i.e., an additional distance equal to the radius of the mortality zone; see Figure 29). This equates to an injury zone of 398.2 m^2. Again, the mortality zone is based on a single observation of a surface detonation in 12 m of water with approximately 5 percent coral cover. We recognize that the range to effects for mortality and injury will likely increase with a decrease in water depth (less than 12 meters) and will likely decrease as water depth increases (greater than 12 meters). We also recognize the explosive weight of the bomb that created the crater was not known. However, we assume it was a relatively large bomb to create a crater of that size 12 meters below the water's surface. As such, smaller bombs would be expected to create a smaller blast-impact area. Also, the magnitude of effects may vary depending on bottom type and bottom features (boulders, shelfs, etc.). For example the percent of hard bottom versus soft bottom environments might influence the amount of refraction of sound pressure waves. Nevertheless, we consider these zones of effect to be representative of a typical scenario at FDM with an average depth and bottom type similar to the 12 meter depth observation.

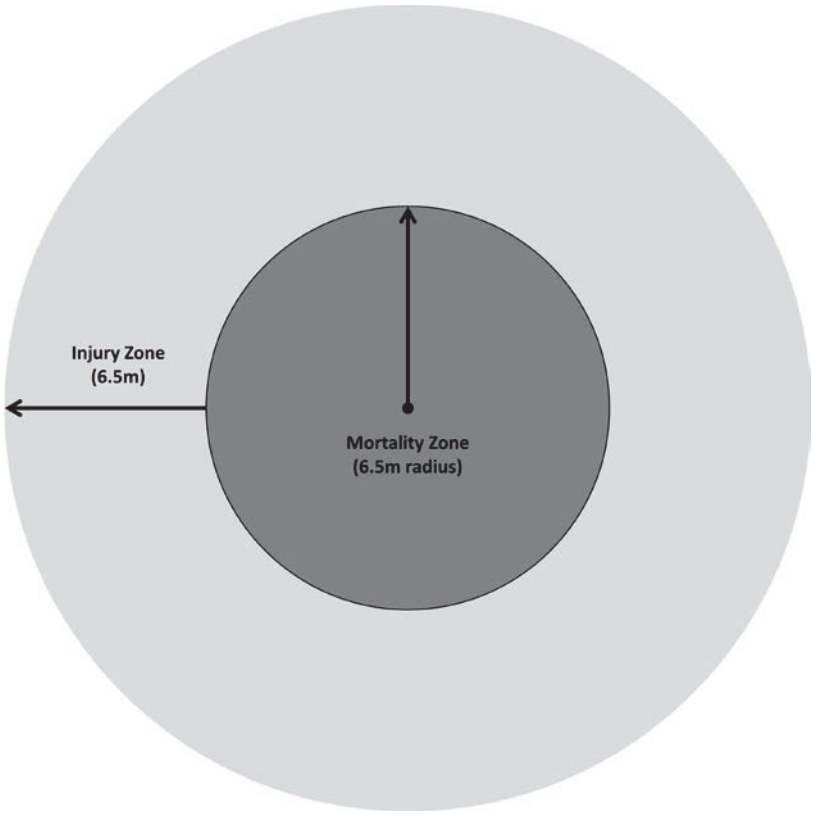

Figure 29. Estimated Injury and Mortality Zones for Coral Colonies Based on a HE Bomb Detonating at the Water's Surface in 12 m of Water

Step Five. Estimate impacts to *Acropora globiceps* from HE Bombs

Next, we used the mortality and injury zones estimated for HE bombs (as determined in Step Four) to estimate the area (m^2) and number of colonies of *Acropora globiceps* impacted. We assumed 18.6 percent live coral coverage (as described in Step One) and patchy, yet uniform distribution of corals. We used our calculated relative proportion of *Acropora globiceps* (also from Step One) to other FDM reef-building corals of 0.0044 and assumed an average colony size of 0.01767 m^2. We first multiplied the estimated total reef area impacted (from Table 66) by the percent live coral coverage to determine the total area of mortality of live coral cover (8,285m^2 x .186 = 1,541m^2). We then multiplied this total area by the relative proportion of *Acropora globiceps* to other FDM reef-building corals to determine the area of impacted *Acropora globiceps* (1,541m^2 x 0.0044 = 6.78 m^2). We then divided this area by the assumed average colony size to estimate the number of annual *Acropora globiceps* colony mortalities (6.78 m^2 ÷ 0.01767 m^2 = 383.7 colonies). Table 67 provides these results.

Table 67. Estimated Annual Mortality From In-Water Explosions of High-explosive Bombs at FDM

Total reef impact area (m^2)	Mortality Zone (Assuming 18.6% Coral Coverage)(m^2)	Apportioned Area for *A globiceps* (m^2); habitat area surrogate	Estimated *Acropora globiceps* Colony Mortalities (Assuming an Average Colony Size of 0.01767 m^2)
8,285.00	1541.01	6.78	383.7 (384[1])

[1]**This number is rounded up to the nearest whole number to provide the total number of individuals killed.**

We performed the same series of calculations to determine the area and number of colonies of *Acropora globiceps* injured from HE bombs. These injuries are expected to be recoverable. The total reef area impacted was estimated by multiplying the number of HE bombs expected to impact reefs (from Table 66) by the area of injury from each bomb, as determined in Step Four (62.42 x 398.2m^2 = 24,855.64 m^2). We then multiplied this area by the percent live coral coverage to determine the total area of injury to live coral (24,855.64m^2 x .186 = 4,623.14m^2). We then multiplied this total area by the relative proportion of *Acropora globiceps* to other FDM reef-building corals to determine the area of injured *Acropora globiceps* (4,623.14m^2 x 0.0044 = 20.34 m^2). Finally, we divided this area by the assumed average colony size to estimate the number of annual *Acropora globiceps* colony mortalities (20.34 m^2 ÷ 0.01767 m^2 = 1,151 colonies). Table 68 provides the results of these calculations.

Table 68. Estimated Recoverable Injury From Direct Strike of Ordnance and Expended Materials at FDM

Total reef impact area (m^2)	Injury Zone (Assuming 18.6% coral coverage) (m^2)	Apportioned Area for *A globiceps* (m^2)	Estimated *Acropora globiceps* Colony Recoverable Injuries (Assuming an Average Colony Size of 0.01767 m^2)
24,855.64	4,623.14	20.34	1,151.2 (1,152[1])

[1]**This number is rounded up to the nearest whole number to provide the total number of individuals injured.**

Step Six. Estimate Instances of Injury of Coral Colonies from Ordnance other than HE Bombs

Next we estimated the number of reasonably expected injuries to *Acropora globiceps* from strikes of inert practice bombs, projectiles and missiles, and military expended materials (bomb, missile, shell fragments). Injuries from live ordnance were estimated in the previous step. Most small caliber projectiles will lose most of their energy upon contact with the water surface and are not expected to impact *Acropora globiceps* with enough force to cause a measurable effect. Table 66 indicates 1,993 strikes to reefs from ordnance other than small-caliber projectiles and HE-bombs are expected to occur annually. To determine how many of these strikes are likely to

impact *Acropora globiceps*, we first multiplied this number of strikes by the average percent of live coral cover (1,993 strikes x 0.186 = 370.7 strikes of live coral). We then multiplied this number by the relative proportion of *Acropora globiceps* to other FDM reef-building corals to determine the number of *Acropora globiceps* colonies struck by ordnance other than HE bombs (370.7 strikes x 0.0044 = 1.6 strikes). Rounding up, this results in an estimate of two *Acropora globiceps* strikes per year from ordnance other than HE-bombs and small caliber projectiles.

Step Seven. Estimate the population size of *Acropora globiceps* around FDM

The contiguous coral reef around FDM covers an estimated 7,725,226 m^2 based on GIS analysis of data from the National Oceanic Service (2004). Given an estimated 18.6 percent coral cover of reefs around FDM and an *Acropora globiceps* abundance proportion of 0.0044 to other coral species this equates to an estimated 6,322.3 m^2 of *Acropora globiceps* live coral area (7,725,226 m^2 x 0.186 = 6,322.3 m^2). Assuming an average colony size of 0.01767 m^2, this area could be inhabited by as many as 357,800 *Acropora globiceps* colonies (6,322.3 m^2 ÷ 0.01767 m^2 = 357,800 colonies).

Step Eight. Compare Mortality and Injury Estimates to FDM Population Estimates and Rangewide Population Estimates

We compared the take estimates calculated in steps five and six to the area and colony estimates from step seven and from the rangewide population estimate for *Acropora globiceps*.

While the above methods can be used to generate rough estimates of the number of *Acropora globiceps* colonies affected by the proposed action, it is not practical to express the amount or extent of anticipated take of individual *Acropora globiceps* colonies, or to monitor take-related impacts in terms of individuals of this species. There are many reasons for this, but the primary ones are species identification uncertainty, and natural spatial and temporal variability in the occurrence and density of listed coral colonies, as described below.

As noted in the final listing rule, Indo-Pacific reef-building coral species are generally difficult to identify, even by experts, because of: (1) The high biodiversity of reef-building corals; (2) the high morphological plasticity in many reef-building coral species; and (3) the different methods used for species identification (NMFS 2014, 79 FR 53852). For example, 13 of the 15 ESA-listed Indo-Pacific coral species, including the three species confirmed in the MITT Action Area, have a moderate or high level of species identification difficulty (Fenner 2014). Thus, even if experts can be hired to survey and monitor Action Area sites, the species-level data is likely to be confounded by species identification uncertainty.

In addition, coral reef communities are highly dynamic whether humans are present or not, with species presence/absence, colony density, colony size and morphology, and other factors varying over small spatial scales (e.g., a few meters separate forereef and backreef habitats, which can have radically different coral communities) and small temporal scales (e.g., seasonal and annual cycles of natural disturbance, like storms and predation events, can wipe out a species or community in a particular area, followed by species recovery). The spatial and temporal variability in coral habitat and species abundance is described in detail in the final rule's Corals

and Coral Reefs section (NMFS 2014, 79 FR 53852). Thus, even if reliable species-level data can be produced for a given Action Area site over time, any changes in species abundance caused by the proposed action are likely to be confounded by natural variability.

Thus, for the proposed action, it is not practical to express the amount or extent of anticipated take of *Acropora globiceps*, or to monitor take-related impacts in terms of individuals of these species. Therefore, the incidental take of *Acropora globiceps* is expressed as a habitat area surrogate for mortality and in instances of injury to this area of habitat assumed to be occupied by *Acropora globiceps* in the Incidental Take Statement, as prescribed by the new NMFS-FWS ITS rule (May 11, 2015; 80 FR 26832).

6.8.10.2.3 Effects of detonations on coral eggs, sperm, and larvae

Acropora globiceps broadcast spawn where fertilization and early embryonic development occurs (See Section 4.2.11.3). The eggs, sperm, and larval stage of *Acropora globiceps* could remain in the water column for extended periods. Each individual polyp of an *Acropora* coral can produce 16 eggs and concentrations of sperm can be as high as 1 million per milliliter of seawater during spawning. Fertilized eggs develop into planula larvae within 5 days in *Acropora* species but these larvae can also remain in the water column over 200 days before settling. It is reasonable to assume in-water detonations occurring around FDM, at the Piti Point Floating Mine Neutralization site, the Agat Bay Mine Neutralization site, and the Outer Apra Harbor UNDET site could affect eggs, sperm, or planula larvae of *Acropora globiceps* (or other ESA-listed coral species) if their presence coincided with an explosion. Life stages subjected to the shearing forces of turbulent shockwaves from underwater detonations could be deformed, die, or experience a decreased likelihood of fertilization. Shock waves in the waters around explosions may reflect off of hard surfaces and the surface of the water, magnifying the exposure of nearby reefs. However, as described above, the reproductive biology of *Acropora globiceps*, and other coral species, results in prolific larval production and high natural mortality from a combination of factors including predation and dispersal to areas within the ocean without appropriate settlement habitat (e.g., deeper or colder water, unsuitable substrate). Any anthropogenic mortality from the Navy's actions is likely to be infinitesimally small by comparison (L. Smith, personal communication, May 6, 2015) and biologically insignificant to reproduction of corals. Additionally, of the 19 threats to coral identified in the 2011 status review report of the 82 candidate coral species petitioned under the U.S. Endangered Species Act (Brainard et al. 2011a) and the top 9 threats to coral analyzed in the final rule (79 FR 53851), none include mortality of larvae by physical contact such as cavitation or explosives, or acoustic effects. While detonations may result in the mortality of the developmental stages of *Acropora globiceps* (and other ESA-listed coral species), it likely would have an insignificant effect on the reproductive potential for an individual colony of the species or recruitment at the population level of this species. Since this level effect is not expected to be signficant and detectable at the individual level (i.e., colony) we would not consider this effect to be a reduction in fitness of any colony of *Acropora globiceps* and thus we do not anticipate any population-level effects.

6.8.10.2.4 Exposure of Corals to Impulsive Acoustic Stressors During Testing

No MITT testing activities will occur at the Outer Apra Harbor UNDET site or on FDM; therefore no exposure of corals to impulsive acoustic stressors during testing is anticipated.

6.8.10.2.5 Response of Corals to Impulsive Acoustic Stressors During Training and Testing

Impacts from explosive ordnance accidentally impacting reefs around FDM will vary with explosive weight but it can be expected local colonies and collections of colonies forming a reefscape would be negatively affected and likely die from such an event. Colonies closest to the blast would likely be killed. The calcium carbonate structure of the reef could also be broken and pulverized by such an event. The resulting changes in coral community structure may reduce ecosystem function in the immediate area of the detonation. However, if not chronically disturbed from subsequent impacts of munitions or natural causes (e.g., storms), coral community structure and ecosystem function would likely return with time. Additionally, the breaking of reefs could also create new habitat for future coral recruitment (Chabanet et al. 2005).

Based on GIS analysis of data from the National Oceanic Service (2004) regarding coral cover around FDM and previous coral reef surveys conducted by the Navy (DoN 2005b), we estimated the area of live *Acropora globiceps* cover around FDM to total 6,322.3 m^2. We also estimated mortality of up to 6.78 m^2 of habitat occupied by live *Acropora globiceps* from Navy explosive ordnance activities around FDM each year. Therefore, we estimate that Navy activities will kill up to 0.11 percent (6.78m^2) of *Acropora globiceps* colonies around the island each year.

In addition to the assessed mortality, our analysis estimated 20.34 m^2 of habitat assumed to be occupied by *Acropora globiceps* will be injured (recoverable injury to approximately 1,152 colonies) from Navy explosive ordnance activities around FDM each year. We also estimated two instances of recoverable injury to habitat assumed to be occupied by *Acropora globiceps* around FDM from ordnance other than high-explosive bombs will occur on an annual basis. Injuries could include varying degrees of abrasion, breakage, and/or pieces of debris settling upon portions of the coral colony. However, because only a portion of the coral colony polyps would be affected, we do not expect injuries to result in coral colony mortality. Uninjured coral polyps within the colony affected would be able to sustain the "individual" as defined in Section 6.5. The tissue thickness of *Acropora* species is 1 to 2 mm thick, considerably thinner than many coral species, which allows them to grow quicker than many other species (Loya et al. 2001). Therefore, injured *Acropora globiceps* colonies would likely be able to bud and develop new polyps to replace those lost in the injury. Fragmentation may also occur where pieces of the coral colony break off, separating a single colony into two or more individuals. Fragmentation may lead to a large number of asexually-produced, genetically identical colonies, commonly resulting in a population made up of more asexually-produced colonies than sexually-produced colonies (Hughes 1984).

These assumptions are supported by Navy coral reef surveys, which indicate military-caused reef damage around FDM is short term and recovery occurs within two to three years. Although individual colonies and clusters of colonies forming a smallscale reefscape may be negatively impacted by impulsive explosions, Navy surveys of FDM reefs suggest no significant population level impacts are likely to occur, and colony repair or successful recruitment will likely occur within two to three years following disturbance.

6.9 Cumulative Effects

Cumulative effects include the effects of future State, tribal, local, or private actions that are reasonably certain to occur in the Action Area considered in this biological opinion. Future Federal actions that are unrelated to the proposed action are not considered in this section because they require separate consultation pursuant to section 7 of the ESA.

During this consultation, NMFS searched for information on future State, tribal, local, or private actions that were reasonably certain to occur in the Action Area. Most of the Action Area includes federal military reserves or is outside of territorial waters of the United States of America, which would preclude the possibility of future state, tribal, or local action that would not require some form of federal funding or authorization. NMFS conducted electronic searches of business journals, trade journals, and newspapers using *First Search*, Google, and other electronic search engines. Those searches produced no evidence of future private action in the Action Area that would not require federal authorization or funding and is reasonably certain to occur. As a result, NMFS is not aware of any actions of this kind that are likely to occur in the Action Area during the reasonably foreseeable future.

7 Integration and Synthesis Of Effects

Our effects analyses identified the probable risks the DoD and USCG training and testing activities and issuance of an MMPA rule and LOA to authorize take of marine mammals would pose to ESA-listed individuals that will be exposed to these actions. We measure risks to individuals of endangered or threatened species using changes in the individuals' "fitness" or the individual's growth, survival, annual reproductive success, and lifetime reproductive success. When we do not expect listed animals exposed to an action's effects to experience reductions in fitness, we would not expect the action to have adverse consequences on the viability of the populations those individuals represent or the species those populations comprise. As a result, if we conclude that listed animals are not likely to experience reductions in their fitness, we would conclude our assessment. If, however, we conclude that listed animals are likely to experience reductions in their fitness, we would assess the consequences of those fitness reductions for the population or populations the individuals in an *Action Area* represent.

The activities the DoD and USCG conducts in the MITT Action Area will continue to introduce a suite of stressors into the marine and coastal ecosystems of the Mariana Islands and the transit lanes to and from the Hawaii Action Area. The stressors include: low, mid, and high-frequency active sonar from surface vessels, torpedoes, and dipping sonar; shock waves and sound fields associated with underwater detonations, acoustic and visual cues from surface vessels as they move through the ocean's surface, and sounds transferred into the water column from fixed-wing aircraft and helicopters. Repeatedly exposing endangered and threatened marine animals to each of these individual stressors could pose additional risks as the exposures accumulate over time. Repeated exposures are discussed in more detail in section 6.2.11 and 6.3.7. Also, exposing endangered and threatened marine animals to this suite of stressors could pose additional risks as the stressors interact with one another or with other stressors that already occur in those areas. More importantly, endangered and threatened marine animals that occur in the MITT Action Area would be exposed to combinations of stressors produced by DoD and USCG activities at

the same time they are exposed to stressors from other human activities and natural phenomena. We recognize these interactions might have effects on endangered and threatened species that we have not considered; however, the data available do not allow us to do more than acknowledge the possibility.

For the purposes of this Opinion, we assume that all of these activities in the MITT Action Area and associated impacts will continue into the reasonably foreseeable future at the levels set forth in the Final EIS/OEIS and MMPA rule. To address the likelihood of long-term additive or accumulative effects, we first considered (1) stressors that accumulate in the environment, and (2) effects that represent either the response of individuals, populations, or species to that accumulation of stressors.

Sound does not permanently accumulate in the environment; therefore, an accumulative effects analysis on this stressor is not warranted. However, repeated exposure of individuals to acoustic stress can cause auditory fatigue and hearing loss. We expect ESA-listed species will not receive repeated exposures at a rate at which recovery between exposures would not occur because of the intermittent nature and duration of Navy acoustic sources. Navy activities on the MITT Action Area involving active sonar or underwater detonations are infrequent, short-term, and generally unit level. Unit level events occur over a small spatial scale (one to a few 10s of square miles) and with few participants (usually one or two). Single-unit unit level training would typically involve a few hours of sonar use, with a typical nominal ping of every 50 seconds (duty cycle). Even though an animal's exposure to active sonar may be more than one time, the intermittent nature of the sonar signal, its low duty cycle, and the fact that both the vessel and animal are moving provide a very small chance that exposure to active sonar for individual animals and stocks would be repeated over extended periods of time. Consequently, the DoD and USCG's MITT activities do not create conditions of chronic, continuous underwater noise and are unlikely to lead to habitat abandonment or long-term hormonal or physiological stress responses in marine mammals.

Although Goldbogen et al. (2013) speculates that "frequent exposures to mid-frequency anthropogenic sounds may pose significant risk to the recovery rates of endangered blue whale populations," the authors acknowlege that the actual responses of individual blue whales to simulated mid-frequency sonar documented in the study "typically involves temporary avoidance responses that appear to abate quickly after sound exposure." Moreover, the most significant response documented in the study occurred not as a result of exposure to simulated mid-frequency sonar but as a result of exposure to pseudo-random noise. Therefore, the overall weight of scientific evidence indicates that substantive behavioral responses by mysticetes, if any, from exposure to mid-frequency active sonar and other active acoustic sources evaluated in this Opinion are likely to be temporary and are unlikely to have any long-term adverse impact on individual animals or affected populations. Even if sound exposure were to be concentrated in a relatively small geographic area over a long period of time (e.g., days or weeks during major training exercises), we would expect that some individual whales would avoid areas where exposures to acoustic stressors are at higher levels (e.g., greater than 120 dB). For example, Goldbogen et al. (2013) indicated some horizontal displacement of deep foraging blue whales in response to simulated MFA sonar. Given these animal's mobility and large ranges, we would expect these individuals to temporaily select alternative foraging sites nearby until the exposure

levels in their initially selected foraging area have decreased. Therefore, even temporary displacement from initially selected foraging habitat is not expected to impact the fitness of any individual animals because we would expect equivalent foraging habitat to be available in close proximity. Because we do not expect any fitness consequences from any individual animals, we do not expect any population level effects from these behavioral responses.

Further, establishing a causal link between anthropogenic noise, animal communication, and individual impacts as well as population viability is difficult to quantify and assess (McGregor 2013) (Read et al. 2014). The difficulty in assessing the effects of sounds individually and cumulatively on marine species is the confounding nature of indirect effects, age class, prior experience, behavioral state at the time of exposure, and that responses may be influenced by other non-sound related factors (Ellison et al. 2011; Goldbogen et al. 2013; Kight and Swaddle 2011; McGregor 2013; Williams et al. 2014) (Read et al. 2014).

Our assessment that the continuation of the Navy activities into the reasonably foreseeable future is unlikely to have any adverse additive or long-term impacts on the affected threatened or endangered species (assuming current levels of activity and no significant changes in the status of species or to the *Environmental Baseline*) is also consistent with the absence of any documented population-level or adverse aggregate impacts resulting from DoD and USCG activities to date, despite decades of training in the MITT Action Area using many of the same systems. Most of the training activities the DoD and USCG conducts in the MITT Action Area are similar, if not identical, to activities that have been occurring in the same locations for decades.

Our regulations require us to consider, using the best available scientific data, effects of the action that are "likely" and "reasonably certain" to occur rather than effects that are speculative or uncertain. See 50 C.F.R. § 402.02 (defining to "jeopardize the continued existence of" and "effects of the action"). Our analysis and conclusions in this Opinion are based on estimates of exposures and take assuming that the DoD and USCG conduct the maximum number of authorized training and testing activities for the maximum number of authorized hours. The effects of the action in relation to the *Status of Listed Resources* and the *Environmental Baseline* are presented by each species below.

7.1.1 Blue Whale

In determining whether U.S. Navy training and testing activities in the MITT Action Area are likely to jeopardize the survival and recovery of blue whales, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources* and, those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any blue whales being exposed to U.S. Navy vessels, sound fields associated with active sonar pings, or shock waves associated with underwater detonations. Those individuals that are exposed would only be so periodically or episodically.

As described in the *Status of Listed Resources* and *Environmental Baseline* sections of this Opinion, some of the primary anthropogenic threats to the survival and recovery of blue whales have been whaling and ship strikes. The threat of whaling has been eliminated. The current abundance trend for blue whales rangewide including the MITT Action Area is not well understood. However, recent evidence indicates that some blue whale populations in the North Pacific may be increasing (Monnahan et al. 2014).

Assuming that the Navy conducts the maximum number of authorized training and testing activities for the maximum number of authorized hours, we estimated that in any given year during the five-year period (August 2015 through August 2020), blue whales could potentially experience up to 28 instances of take in the form of behavioral harassment and TTS resulting from non-impulsive acoustic stressors. Of those 28 instances of behavioral harassment, we anticipate no more than of 3 takes per year in the form of TTS. We do not anticipate any take in the form of injury from PTS or other injuries such as GI tract or lung injury during annual training or testing activities. We do not anticipate any mortality of blue whales from MITT stressors. The estimates of exposures to training and testing exercises that would result in behavioral responses (including instances of TTS) annually would not be expected to appreciably reduce the likelihood of the survival of blue whales in the wild by reducing the reproduction, numbers, or distribution of that species for the reasons discussed herein.

While we recognize that animal hearing evolved separately from animal vocalizations and, as a result, it may be inappropriate to make inferences about an animal's hearing sensitivity from their vocalizations, we have no data on blue whale hearing so we assume that blue whale vocalizations are partially representative of their hearing sensitivities. Blue whales are not likely to respond to high-frequency sound sources associated with the proposed training exercises and testing activities because of their hearing sensitivities. Despite previous assumptions based on vocalizations and anatomy that blue whales predominantly hear low-frequency sounds below 400 Hz (Croll et al. 2001b) (Oleson et al., 2007; Stafford and Moore, 2005), recent research has indicated blue whales not only hear mid-frequency active sonar transmissions, in some cases they respond to those transmissions (Southall et al. 2011a).

Blue whales may hear some sounds in the mid-frequency range and exhibit behavioral responses to sounds in this range depending on received level and context (Goldbogen et al. 2013 and Melcon et al. 2012). However, both Goldbogen et al (2013) and Melcon et al. (2012) indicated that behavioral responses to simulated or operational MFA sonar were temporary, with whales resuming normal behavior quickly after the cessation of sound exposure. Further, responses were discernible for whales in certain behavioral states (i.e., deep feeding), but not in others (i.e., surface feeding). As stated in Goldbogen et al. (2013) when summarizing the response of blue whales to simulated MFA sonar, "We emphasize that elicitation of the response is complex, dependent on a suite of contextual (e.g., behavioral state) and sound exposure factors (e.g., maximum received level), and typically involves temporary avoidance responses that appear to abate quickly after sound exposure." Goldbogen et al. (2013) also speculated that if this temporary behavioral response interrupted feeding behavior, this could have impacts on individual fitness and eventually, population health. However, for this to be true, we would have to assume that an individual whale could not compensate for this lost feeding opportunity by either immediately feeding at another location, by feeding shortly after cessation of acoustic

exposure, or by feeding at a later time. Additionally, in instances of TTS, individuals would likely fully recover within 24 hours of exposure and resume normal behavioral activities. There is no indication, particularly since unconsumed prey would still be available in the environment following the cessation of acoustic exposure and resumption of normal behaviors following instances of behavioral response including responses associated with TTS.

During the Controlled Exposure Experiments (CEEs) used in Goldbogen et al. (2013), sound sources were deployed from a stationary source vessel positioned approximately 1,000 m from the focal animals, with one transmission onset every 25 seconds (Southall et al. 2012). In contrast, most Navy sonar systems are deployed from highly mobile vessels or in-water devices which do not directly target marine mammals. Further, the typical duty cycle with most tactical anit-submarine warefare is lower than used in the CEEs described above, transmitting about once per minute (DoN 2015). For example, a typical Navy vessel with hull mounted MFA sonar would travel over 0.3 kilometers between pings (based on a speed of 10 knots/hr and transmission rate of 1 ping/min). Based on this distance traveled and potential avoidance behavior of acoustically exposed animals, we expect repeat acoustic exposures capable of eliciting a behavioral response to an individual over a brief period of time to be rare. In the event an individual is exposed to multiple sound sources that elicit a behavioral response (e.g., disruption of feeding) in a short amount of time, including instances of TTS, we do not expect these exposures to have fitness consequences as individuals will resume feeding upon cessation of the sound exposure and unconsumed prey will still be available in the environment.

Even if sound exposure were to be concentrated in a relatively small geographic area over a long period of time (e.g., days or weeks during major training exercises), we would expect that some individual whales would avoid areas where exposures to acoustic stressors are at higher levels (e.g., greater than 120 dB). For example, Goldbogen et al. (2013) indicated some horizontal displacement of deep foraging blue whales in response to simulated MFA sonar. Given these animal's mobility and large ranges, we would expect these individuals to temporaily select alternative foraging sites nearby until the exposure levels in their initially selected foraging area have decreased. Therefore, even temporary displacement from initially selected foraging habitat is not expected to impact the fitness of any individual animals because we would expect equivalent foraging to be available in close proximity. Because we do not expect any fitness consequences from any individual animals, we do not expect any population level effects from these behavioral responses.

Most of the blue whales that are exposed to acoustic stressors would be exposed periodically or episodically over certain months or seasons from military activities in the MITT Action Area. Given the nature of testing and training as described above, these periodic or episodic exposure and behavioral response scenarios, including TTS, most often allow sufficient time to return to baseline conditions and resumption of normal behavioral activities such as feeding and breeding. As described previously, including in Sections 6.2.11 and 6.8.3.2.1 of this Opinion, the available scientific information does not provide evidence that exposure to acoustic stressors from Navy training and testing activities will impact the fitness of any individuals of this species. Therefore exposure to acoustic stressors will not have population or species level impacts.

Further, recent evidence indicates that the Eastern North Pacific blue whale population, has likely reached carrying capacity (Monnahan et al. 2014). Navy training and testing activities, including the use of MFA sonar, have been ongoing in this area for decades. Therefore, any potential temporary behavioral impacts on blue whales from the use of MFA during Navy training and testing activities do not appear to have inhibited population growth of the Eastern North Pacific blue whale population in that area. We would expect similar effects to exist in the MITT Action Area.

The 1998 blue whale recovery plan does not outline downlisting or delisting criteria. The recovery plan does list several stressors potentially affecting the status of blue whales in the North Pacific Ocean that are relevant to MITT activities including: vessel strike, vessel disturbance, and military operations (including sonar). At the time the recovery plan was published, the effects of these stressors on blue whales in the Pacific Ocean were not well documented, their impact on recovery was not understood, and no attempt was made to prioritize the importance of these stressors on recovery. As described previously, anthropogenic noise associated with MITT activities is not expected to impact the fitness of any individuals of this species. No mortality of blue whales is expected to occur from MITT activities.

Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the DoD and USCG will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of blue whales in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing Navy training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of blue whales in the wild by reducing the reproduction, numbers, or distribution of that species. MITT stressors will not affect the population dynamics, behavioral ecology, and social dynamics of individual blue whales in ways or to a degree that would reduce their fitness. We anticipate temporary behavioral responses, but do not anticipate any injury or mortality from acoustic stressors. We do not anticipate those behavioral responses to result in fitness consequences to any individuals and therefore, we do not expect acoustic stressors to result in substantial changes in reproduction, numbers, or distribution of these populations. An action that is not likely to reduce the fitness of individual whales would not be likely to reduce the viability of the populations those individual whales compose (that is, we would not expect reductions in the reproduction, numbers, or distribution of those populations). We do not anticipate any reductions in survival rate or trajectory of recovery of the species as listed pursuant to the ESA that would be sufficient to be readily perceived or estimated.

7.1.2 Fin Whale

In determining whether U.S. Navy training and testing activities in the MITT Action Area are likely to jeopardize the survival and recovery of fin whales, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources* and, those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many

U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any fin whales being exposed to U.S. Navy vessels, sound fields associated with active sonar pings, or shock waves associated with underwater detonations. Those individuals that are exposed would only be so periodically or episodically.

Assuming that the Navy conducts the maximum number of authorized training and testing activities for the maximum number of authorized hours, we estimated that in any given year during the five-year period (August 2015 through August 2020), fin whales could potentially experience up to 28 instances of take in the form of behavioral harassment and TTS resulting from non-impulsive acoustic stressors. Of those 28 instances of behavioral harassment, we anticipate no more than 4 takes per year in the form of TTS resulting from non-impulsive sound stressors. We anticipate zero take by injury in the form of permanent threshold shift (PTS) or other injuries such as GI tract or lung injury from annual training and testing activities. We do not anticipate any mortality of fin whales from MITT stressors. The estimates of exposures to training and testing exercises that would result in behavioral responses (including instances of TTS) annually would not be expected to appreciably reduce the likelihood of the survival of fin whales in the wild by reducing the reproduction, numbers, or distribution of that species for the reasons discussed herein.

Frequencies associated with mid-frequency sonar have generally been considered above the hearing range of fin whales. However, recent observations of blue whale responses to the mid-frequency sonar sounds support the possibility that this ecologically, physiologically, and taxonomically similar species may be capable of detecting and responding to them. Additional data are necessary to determine the potential impact that mid-frequency sonar may or may not have on fin whales. Considering information presented in this opinion, we consider fin whales to be able to hear and respond to mid-frequency sonar as blue whales appear to.

Most of the fin whales that are exposed to acoustic stressors would be exposed periodically or episodically over certain months or seasons from military activities in the MITT Action Area. Given the nature of testing and training as described above, these periodic or episodic exposure and behavioral response scenarios, including responses to TTS, most often allow sufficient time to return to baseline conditions and resumption of normal behavioral activities such as feeding and breeding. Individuals exposed to acoustic stressors at levels resulting in TTS will likely fully recover within 24 hours of the exposure and resume normal behaviors including feeding. As described previously, including in Sections 6.2.11 and 6.8.3.2.1 of this Opinion, the available scientific information does not provide evidence that exposure to acoustic stressors from Navy training and testing activities will impact the fitness of any individuals of this species. Therefore exposure to acoustic stressors will not have population or species level impacts.

The 2010 fin whale recovery plan defines three recovery populations by ocean basin (the North Atlantic, North Pacific, and Southern Hemisphere) and sets criteria for the downlisting and delisting of this species. Both downlisting and delisting requirements include abatement of threats associated with fisheries, climate change, direct harvest, anthropogenic noise, and ship collision. Of these, anthropogenic noise and ship collision are relevant to MITT activities. As discussed previously, anthropogenic noise associated with MITT activities will not impact the

fitness of any individuals of this species. Downlisting criteria for fin whales includes the maintenance of at least 250 mature females and 250 mature males in each recovery population, which is already exceeded in the North Pacific. To qualify for downlisting, each recovery population must also have no more than a 1 percent chance of extinction in 100 years. To qualify for delisting, each recovery population must also have no more than a 10 percent chance of becoming endangered in 20 years. To our knowledge a population viability analysis has not been conducted on fin whale recovery populations.

Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the DoD and USCG will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of fin whales in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of fin whales in the wild by reducing the reproduction, numbers, or distribution of that species. MITT stressors will not affect the population dynamics, behavioral ecology, and social dynamics of individual fin whales in ways or to a degree that would reduce their fitness. An action that is not likely to reduce the fitness of individual whales would not be likely to reduce the viability of the populations those individual whales represent (that is, we would not expect reductions in the reproduction, numbers, or distribution of those populations). We do not anticipate any reductions in survival rate or trajectory of recovery of the species as listed pursuant to the ESA that would be sufficient to be readily perceived or estimated.

7.1.3 Humpback Whale

In determining whether U.S. Navy training and testing activities in the MITT Action Area are likely to jeopardize the survival and recovery of humpback whales, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources* and, those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any humpback whales being exposed to U.S. Navy vessels, sound fields associated with active sonar pings, or shock waves associated with underwater detonations. Those individuals that are exposed would only be so periodically or episodically.

Assuming that the Navy conducts the maximum number of authorized training and testing activities for the maximum number of authorized hours, we estimated that in any given year during the five year period (August 2015 through August 2020), humpback whales could potentially experience up to 860 instances of behavioral harassment and TTS resulting from non-impulsive acoustic stressors. Of those 860 instances, we anticipate no more than 679 instances per year of harassment in the form of TTS resulting from non-impulsive sound stressors. We anticipate zero instances of injury in the form of PTS or other injuries such as GI tract or lung injury from annual training and testing activities. We do not anticipate any mortality of

humpback whales from MITT stressors. The estimates of exposures to training exercises and exposures to testing exercises that would result in behavioral responses (including instances of TTS) annually would not be expected to appreciably reduce the likelihood of the survival of humpback whales in the wild by reducing the reproduction, numbers, or distribution of that species for the reasons discussed herein.

Frequencies associated with mid-frequency sonar have generally been considered above the hearing range of humpback whales. However, recent observations of blue whale responses to the mid-frequency sonar sounds support the possibility that this ecologically, physiologically, and taxonomically similar species may be capable of detecting and responding to them. Additional data are necessary to determine the potential impact that mid-frequency sonar may or may not have on humpback whales. Considering information presented in this opinion, we consider humpback whales to be able to hear and respond to mid-frequency sonar similar to blue whales.

Most of the humpback whales that are exposed to acoustic stressors would be exposed periodically or episodically over certain months or seasons from military activities in the MITT Action Area. Given the nature of testing and training as described above, these periodic or episodic exposure and behavioral response scenarios, including responses to TTS, most often allow sufficient time to return to baseline conditions and resumption of normal behavioral activities such as feeding and breeding. As described previously, including in Sections 6.2.11 and 6.8.3.2.1 of this Opinion, the available scientific information does not provide evidence that exposure to acoustic stressors from Navy training and testing activities will impact the fitness of any individuals of this species. Therefore exposure to acoustic stressors will not have population or species level impacts.

The general increase in the number of humpback whales range-wide suggests that the stress regime these whales are exposed to including activities in the MITT Action Area have not prevented these whales from increasing their numbers. Humpback whales have been exposed to U.S. Navy training exercises in the MITT Action Area, including vessel traffic, aircraft traffic, active sonar, and underwater detonations, for more than a generation. Although the U.S. Navy proposes to increase the frequency of some of these activities, we do not believe those increases are likely to affect the rate at which humpback whale counts are increasing.

The 1991 humpback whale recovery plan does not outline specific downlisting and delisting criteria. The recovery plan does list several threats known or suspected of impacting humpback whale recovery including subsistence hunting, commercial fishing stressors, habitat degradation, loss of prey species, ship collision, and acoustic disturbance. Of these, ship collision and acoustic disturbance are relevant to MITT activities. As described previously, anthropogenic noise associated with MITT activities will not impact the fitness of any individuals of this species.

Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the DoD and USCG will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of humpback whales in the wild

by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing U.S. Navy training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of humpback whales in the wild by reducing the reproduction, numbers, or distribution of that species. MITT stressors will not affect the population dynamics, behavioral ecology, and social dynamics of individual humpback whales in ways or to a degree that would reduce their fitness. An action that is not likely to reduce the fitness of individual whales would not be likely to reduce the viability of the populations those individual whales represent (that is, we would not expect reductions in the reproduction, numbers, or distribution of those populations). We do not anticipate any reductions in survival rate or trajectory of recovery of the species as listed pursuant to the ESA that would be sufficient to be readily perceived or estimated. Due to a lack of fitness consequences to individuals and the populations they represent, we also do not anticipate any reductions in survival rate or trajectory of recovery of the Western North Pacific DPS as currently proposed.

7.1.4 Sei Whale

In determining whether U.S. Navy training and testing activities in the MITT Action Area are likely to jeopardize the survival and recovery of sei whales, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources* and, those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any sei whales being exposed to U.S. Navy vessels, sound fields associated with active sonar pings, or shock waves associated with underwater detonations. Those individuals that are exposed would only be so periodically or episodically.

Assuming that the Navy conducts the maximum number of authorized training and testing activities for the maximum number of authorized hours, we estimated that in any given year during the five year period (August 2015 through August 2020), sei whales could potentially experience up to 319 instances of behavioral harassment and TTS resulting from non-impulsive acoustic stressors. Of those 319 instances of behavioral harassment, we anticipate no more than 258 instances per year of harassment in the form of TTS resulting from non-impulsive sound stressors. We anticipate zero instances of injury in the form of PTS resulting from non-impulsive acoustic stressors or other injuries such as GI tract or lung injury from annual training and testing activities. We do not anticipate any mortality of sei whales from MITT stressors. The estimates of exposures to training exercises and exposures to testing exercises that would result in behavioral responses (including instances of TTS) annually would not be expected to appreciably reduce the likelihood of the survival of sei whales in the wild by reducing the reproduction, numbers, or distribution of that species for the reasons discussed herein.

Frequencies associated with mid-frequency sonar have generally been considered above the hearing range of sei whales. However, recent observations of blue whale responses to the mid-frequency sonar sounds support the possibility that this ecologically, physiologically, and taxonomically similar species may be capable of detecting and responding to them. Additional data are necessary to determine the potential impact that mid-frequency sonar may or may not

have on sei whales. Considering information presented in this opinion, we consider sei whales to be able to hear and respond to mid-frequency sonar similar to blue whales.

Most of the sei whales that are exposed to acoustic stressors would be exposed periodically or episodically over certain months or seasons from military activities in the MITT Action Area. Given the nature of testing and training as described above, these periodic or episodic exposure and behavioral response scenarios, including responses to TTS, most often allow sufficient time to return to baseline conditions and resumption of normal behavioral activities such as feeding and breeding. Individuals experiencing TTS are likely to fully recover within 24 hours of exposure and return to normal behaviors. As described previously, including in Sections 6.2.11 and 6.8.3.2.1 of this Opinion, the available scientific information does not provide evidence that exposure to acoustic stressors from Navy training and testing activities will impact the fitness of any individuals of this species. Therefore exposure to acoustic stressors will not have population or species level impacts.

The 2011 sei whale recovery plan defines three recovery populations by ocean basin (the North Atlantic, North Pacific, and Southern Hemisphere) and sets criteria for the downlisting and delisting of this species. Both downlisting and delisting requirements include abatement of threats associated with fisheries, climate change, direct harvest, anthropogenic noise, and ship collision. Of these, anthropogenic noise and ship collision are relevant to MITT activities. As described previously, anthropogenic noise associated with MITT activities will not impact the fitness of any individuals of this species. Downlisting criteria for fin whales includes the maintenance of 1,500 mature, reproductive individuals with at least 250 mature females and 250 mature males in each recovery population, which is already exceeded in the North Pacific. To qualify for downlisting, each recovery population must also have no more than a 1 percent chance of extinction in 100 years. To qualify for delisting, each recovery population must also have no more than a 10 percent chance of becoming endangered in 20 years. To our knowledge a population viability analysis has not been conducted on sei whale recovery populations.

Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the DoD and USCG will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of sei whales in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of sei whales in the wild by reducing the reproduction, numbers, or distribution of that species. MITT stressors will not affect the population dynamics, behavioral ecology, and social dynamics of individual sei whales in ways or to a degree that would reduce their fitness. An action that is not likely to reduce the fitness of individual whales would not be likely to reduce the viability of the populations those individual whales represent (that is, we would not expect reductions in the reproduction, numbers, or distribution of those populations). We do not anticipate any reductions in survival rate or trajectory of recovery of the species as listed pursuant to the ESA that would be sufficient to be readily perceived or estimated.

7.1.5 Sperm Whale

In determining whether U.S. Navy training and testing activities in the MITT Action Area are likely to jeopardize the survival and recovery of sperm whales, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources* and, those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any sperm whales being exposed to U.S. Navy vessels, sound fields associated with active sonar pings, or shock waves associated with underwater detonations. Those individuals that are exposed would only be so periodically or episodically.

Assuming that the Navy conducts the maximum number of authorized training and testing activities for the maximum number of authorized hours, we estimated that in any given year during the five-year period (August 2015 through August 2020), sperm whales could potentially experience up to 506 instances of take in the form of behavioral harassment and TTS resulting from non-impulsive acoustic stressors. Of these 506 instances of behavioral harassment, we anticipate no more than 54 takes per year in the form of TTS resulting from non-impulsive sound stressors. We do not anticipate any take in the form of injury from PTS or other injuries such as GI tract or lung injury during annual training and testing activities. We do not anticipate any mortality of sperm whales from stressors associated with MITT activities. The estimates of exposures to training exercises and exposures to testing exercises that would result in behavioral responses (including instances of TTS) annually would not be expected to appreciably reduce the likelihood of the survival of sperm whales in the wild by reducing the reproduction, numbers, or distribution of that species for the reasons discussed herein.

Most of the sperm whales that are exposed to acoustic stressors would be exposed periodically or episodically over certain months or seasons from military activities in the MITT Action Area. Given the nature of testing and training as described above, these periodic or episodic exposure and behavioral response scenarios, including responses to TTS, most often allow sufficient time to return to baseline conditions and resumption of normal behavioral activities such as feeding and breeding. Indivudals experiencing TTS will likely fully recover within 24 hours and resume normal behaviors. As described previously, including in Sections 6.2.11 and 6.8.3.2.5 of this Opinion, the available scientific information does not provide evidence that exposure to acoustic stressors from Navy training and testing activities will impact the fitness of any individuals of this species. Therefore exposure to acoustic stressors will not have population or species level impacts.

The 2010 sperm whale recovery plan defines three recovery populations by ocean basin (the Atlantic Ocean/Mediterranean Sea, Pacific Ocean, and Indian Ocean) and sets criteria for the downlisting and delisting of this species. Both downlisting and delisting requirements include abatement of threats associated with fisheries, climate change, direct harvest, oil spills, anthropogenic noise, and ship collision. Of these, anthropogenic noise and ship collision are relevant to MITT activities. As discussed previously, anthropogenic noise associated with MITT activities will not impact the fitness of any individuals of this species. Downlisting criteria for sperm whales includes the maintenance of 1,500 mature, reproductive individuals with at least

250 mature females and 250 mature males in each recovery population, which is already exceeded in the North Pacific. To qualify for downlisting, each recovery population must also have no more than a 1 percent chance of extinction in 100 years. To qualify for delisting, each recovery population must also have no more than a 10 percent chance of becoming endangered in 20 years. To our knowledge a population viability analysis has not been conducted on spern whale recovery populations.

Based on the evidence available, including the environmental baseline and cumulative effects, we conclude that impulsive and non-impulsive acoustic stressors resulting from training exercises and testing activities the DoD and USCG plans to conduct in the MITT Action Area on an annual basis, or cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the status of the species or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of sei whales in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of sperm whales in the wild by reducing the reproduction, numbers, or distribution of that species. MITT stressors will not affect the population dynamics, behavioral ecology, and social dynamics of individual sperm whales in ways or to a degree that would reduce their fitness. An action that is not likely to reduce the fitness of individual whales would not be likely to reduce the viability of the populations those individual whales represent (that is, we would not expect reductions in the reproduction, numbers, or distribution of those populations). We do not anticipate any reductions in survival rate or trajectory of recovery of the species as listed pursuant to the ESA that would be sufficient to be readily perceived or estimated.

7.1.6 Sea Turtles

In determining whether U.S. Navy training and testing activities in the HSTT Action Area are likely to jeopardize the survival and recovery of sea turtles, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources,* and those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any sea turtles being exposed to U.S. Navy vessels, sound fields associated with active sonar pings, or shock waves associated with underwater detonations. Those individuals that are exposed would only be so periodically or episodically.

As described in the *Status of Listed Resources* and *Environmental Baseline* sections of this Opinion, the primary anthropogenic threats to the survival and recovery of sea turtles are overharvest (directed harvest of both eggs and adults), incidental capture in commercial fisheries, and human development of coastlines. Harvest of sea turtles has been greatly reduced in some locations, though it still occurs in other parts of the world, including areas in the Pacific Ocean. Further, efforts have been made in some areas to reduce incidental capture in fisheries, but the problem persists. For some sea turtles (i.e., leatherbacks and loggerheads), available information

indicates that population abundances in the North Pacific Ocean are low enough to experience the dynamics of small population sizes. However, the degree to which this, versus other exogenous threats, contributes to the decline, or inhibits recovery, of these species is unknown.

The predicted acoustic impacts on sea turtles from training and testing activities are shown in Table 58 and Table 63. The exposure estimates represent the total number of exposures and not necessarily the number of individuals exposed, as a single individual may be exposed multiple times over the course of a year. The predicted acoustic impacts do not take into account avoidance behavior or mitigation measures, such as establishing shut-down zones for certain sonar systems.

Approximately 12,500 explosives would be used during training and testing activities per year and would occur in areas designated for use of explosives within the Action Area. Approximately 10,000 (or 80 percent) of the explosives used in the Action Area are in source class E1 (0.1 to 0.25 lb. NEW). Other than those on FDM, most detonations would occur beyond approximately 12 nm from shore, minimizing impacts near nesting beaches or coastal habitats for sea turtles. A small number of near-shore (within 3 nm) training activities could occur, potentially exposing some sea turtles approaching nesting beaches to impulse sounds over a short duration if the training occurred during nesting season or close to sea turtles nearshore habitats. The terrain of FDM does not provide any nesting beaches so effects are not expected at this location to nesting turtles.

Little is known about how sea turtles use sound in their environment. Based on knowledge of their sensory biology (Moein Bartol and Ketten 2006; Bartol and Musick 2003), sea turtles may be able to detect objects within the water column (e.g., vessels, prey, predators) via some combination of auditory and visual cues. However, research examining the ability of sea turtles to avoid collisions with vessels shows they may rely more on their vision than auditory cues (Hazel et al. 2007). Similarly, while sea turtles may rely on acoustic cues to identify nesting beaches, they appear to rely on other non-acoustic cues for navigation, such as magnetic fields (Lohmann and Lohmann 1996a, b) and light (Avens and Lohmann 2003). Additionally, they are not known to produce sounds underwater for communication.

Further, although the information on the hearing capabilities of sea turtles is limited, the information available suggests that the auditory capabilities of sea turtles are centered in the low-frequency range (<2 kHz) (Bartol et al. 1999b; Dow Piniak et al. 2012; Lenhardt et al. 1983; Lenhardt et al. 1994a; Martin et al. 2012; O'Hara and Wilcox 1990; Ridgway et al. 1969), with greatest sensitivity below 1 kHz.

As described in sections 6.3.6, potential behavioral responses of sea turtles to anthropogenic sound could include startle reactions, disruption of feeding, disruption of migration, changes in respiration, alteration of swim speed, alteration of swim direction, and area avoidance. Any disruptions are expected to be temporary in nature, with the animal resuming normal behaviors shortly after the exposure. To result in significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no

indication this is the case, particularly since foraging habitat would still be available in the environment following the cessation of acoustic exposure. Similarly, we expect temporary disruptions of migration and swim speed or direction to be inconsequential because they can resume these behaviors almost immediately following the cessation of the sound exposure. Further, these sorts of behavioral disruptions may be similar to natural disruptions such those resulting from predator avoidance, or fluctuations in oceanographic conditions. Therefore, behavioral responses of sea turtles to acoustic stressors are unlikely to lead to fitness consequences and long-term implications for the population.

We assume that acoustic stressors from Navy training and testing activities conducted during the five-year MMPA rule and into the reasonably foreseeable future are likely to cause TTS and PTS in ESA-listed sea turtles in the MITT Action Area at the levels described above. However, as described previously in sections 6.3.3 and 6.8.4.4, there is no evidence that TTS or PTS results in energetic effects to individual sea turtles or would be likely to significantly reduce the viability of the population these individuals represent. Given that sea turtles do not rely on acoustic cues for most important life functions, it is anticipated that TTS and PTS will not result in fitness consequences to individuals or the populations to which they belong.

Acoustic stressors associated with the Navy's activities in the MITT Action Area also have the ability to cause slight lung injury in ESA-listed sea turtles in the MITT Action Area. As described previously in section 6.8.4.4, although slight lung injuries could temporarily affect the fitness of affected individuals by reducing their respiration rate, these effects are expected to stop once the injury has healed. Therefore, a temporary disruption of behaviors or fitness levels resulting from slight lung injury is not expected to substantially impact individual turtles when considering their overall lifetime fitness. Because we do not expect fitness consequences to individual turtles, we do not expect impacts to populations composed of those individual turtles.

Most of the sea turtles that are exposed to acoustic stressors would be exposed periodically or episodically over certain months or seasons when the Navy is training and testing in the Action Area. These periodic or episodic exposure and response scenarios most often allow sufficient time for the affected individuals to return to baseline conditions and resumption of normal behavioral activities. As described previously in Section 6.3.7, available scientific information does not provide evidence that exposure of sea turtles to acoustic stressors leading to sub-lethal effects from Navy training and testing activities will reduce the fitness of any individuals of this species. The potential for population level impacts resulting from lethal exposure of sea turtles to acoustic stressors is considered in the sections below, along with lethal vessel strike.

7.1.6.1 Green Sea Turtle

Based on our risk analysis on annual training and testing activities, we conclude that in any given year during the five-year period (August 2015 through August 2020), green sea turtles could potentially experience take in the form of behavioral harassment resulting from non-impulsive and impulsive acoustic stressors. As described in sections 6.3.6, 6.8.4.4, and 6.8.8.5, potential behavioral responses of sea turtles to anthropogenic sound could include startle reactions, disruption of feeding, disruption of migration, changes in respiration, alteration of swim speed, alteration of swim direction, and area avoidance. Any disruptions are expected to be temporary in nature, with the animal resuming normal behaviors shortly after the exposure. To result in

significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no indication this is the case, particularly since foraging habitat would still be available in the environment following the cessation of acoustic exposure. Similarly, we expect temporary disruptions of migration and swim speed or direction to be inconsequential because they can resume these behaviors almost immediately following the cessation of the sound exposure. Further, these sorts of behavioral disruptions may be similar to natural disruptions such those resulting from predator avoidance, or fluctuations in oceanographic conditions. Therefore, behavioral responses of sea turtles to acoustic stressors are unlikely to lead to fitness consequences and long-term implications for the population.

We anticipate approximately 1,837 instances of exposure to impulsive acoustic stressors that may result in behavioral harassment. We do not anticipate any additional exposures to non-impulsive acoustic stressors that might result in purely behavioral responses that were not also assessed as part of the instances of TTS, PTS, or injury. Additionally, we expect no more than 262 takes per year in the form of TTS resulting from impulsive (11 instances) and non-impulsive (251 instances) sound stressors. We anticipate one take each year during the five-year period in the form of PTS from impulsive sound sources. We also estimate approximately three (3) injuries in the form of slight lung injury and one (1) mortality from acoustic stressors that could occur in a given year. We also aniticipate the mortality of one green sea turtle from vessel strikes in a given year.

Death of an individual sea turtle would have a direct fitness consequence to the individual leading to lost reproductive potential that the individual might contribute to the population or sub-population. This lost reproductive potential will vary depending on the sex (male or female) and maturity of the individual. The death of a male would have less of an effect on the population than the loss of a female. Loss of a sexually mature female will have immediate effects on recruitment while lost reproductive potential from mortality of a juvenile female might not be realized for several years.

As stated previously in Section 4.2.6.9, the threatened green sea turtle population (the population that includes turtles in the MITT Action Area) is estimated to lay approximately 109,000 nests annually. On average green turtles nest every 2, 3 or 4 years, and lay 3.3 nests each year they breed (USFWS 2012a). Conservatively assuming that most turtles nest every 2 years, this equates to a likely total population size of approximately 66,000 females (if we assume the turtles nest every 4 years, the total population size is approximately 132,000 females). Removing 2 females from this population in one year would reduce the reproductive potential of this population by 0.002 percent. We do not consider this an appreciable reduction in the numbers of female green turtles or the reproductive rate of the population, either on an annual basis or continuing into the reasonably foreseeable future. Because we do not expect this level of mortality to result in an appreciable reduction in the numbers or reproductive rate of the threatened population of green sea turtles, we do not expect this level of mortality to impact the survival or recovery of this population.

The proposed Central West Pacific DPS of green sea turtles has an estimated 6,500 nesting females. Removing two females from this population in one year would reduce the reproductive potential of this population by 0.03 percent. We do not consider this an appreciable reduction in the numbers of female green turtles or the reproductive rate of this proposed DPS, either on an annual basis or continuing into the reasonably foreseeable future. Because we do not expect this level of mortality to result in an appreciable reduction in the numbers or reproductive rate of the proposed endangered Central West Pacific DPS of green sea turtles, we do not expect this level of mortality to impact the survival or recovery of this population.

The 1998 recovery plan for the threatened U.S. Pacific population of green sea turtles identifies directed take (poaching), coastal construction, and increased human presence as major threats occurring within the Action Area, and sets criteria for the delisting of this entity. These stressors are not associated with MITT activities analyzed in this Opinion. Neither vessel collision or acoustic stressors were identified as stressors affecting recovery in Guam or the CNMI. Delisting requires identifying regional stocks to source beaches, maintenance of stocks above 5,000 nesting females annually, nesting populations at source beaches are stable or increasing for 25 years, maintenance of healthy foraging areas, increases of foraging populations, completion of all priority one tasks, and the finalization of management plans and international agreements. However, we do not have sufficient information to assign sea turtles killed by DoD and USCG activities to individual nesting populations. Because of this, we considered the entirety of the listed entity, and concluded the removal of two green sea turtles annually from acoustic stressors and vessel strike and continuing at this rate into the reasonably foreseeable future is not an appreciable reduction in the numbers or the reproductive capability of the species. As a proposed DPS, the Central West Pacific population does not have a recovery plan.

Based on our analysis in this Opinion, we conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of the survival of green sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of green sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. That is, acoustic stressors will not have fitness consequences and vessel strike will not result in an appreciable reduction in reproductive capability at the population or range-wide level. Therefore, we do not anticipate any measurable or detectable reductions in survival rate or trajectory of recovery of the proposed Central West Pacific DPS or to the species as currently listed pursuant to the ESA.

7.1.6.2 Hawksbill sea turtle

Based on our risk analysis on annual training and testing activities, we conclude that in any given year during the five-year period (August 2015 through August 2020), hawksbill sea turtles could potentially experience take in the form of behavioral harassment resulting from non-impulsive and impulsive acoustic stressors. As described in sections 6.3.6, 6.8.4.4, and 6.8.8.5, potential behavioral responses of sea turtles to anthropogenic sound could include startle reactions, disruption of feeding, disruption of migration, changes in respiration, alteration of swim speed, alteration of swim direction, and area avoidance. Any disruptions are expected to be temporary

in nature, with the animal resuming normal behaviors shortly after the exposure. To result in significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no indication this is the case, particularly since foraging habitat would still be available in the environment following the cessation of acoustic exposure. Similarly, we expect temporary disruptions of migration and swim speed or direction to be inconsequential because they can resume these behaviors almost immediately following the cessation of the sound exposure. Further, these sorts of behavioral disruptions may be similar to natural disruptions such those resulting from predator avoidance, or fluctuations in oceanographic conditions. Therefore, behavioral responses of sea turtles to acoustic stressors are unlikely to lead to fitness consequences and long-term implications for the population.

We anticipate approximately 129 instances of exposure to impulsive acoustic stressors that may result in behavioral harassment. We do not anticipate any additional exposures to non-impulsive acoustic stressors that might result in purely behavioral responses that were not counted as TTS, PTS, or injury. Additionally, we anticipate no more than 20 takes per year in the form of harassment from TTS resulting from impulsive (3 instances) and non-impulsive (17 instances) sound stressors. We anticipate zero takes each year during the five-year period in the form of PTS from impulsive sound sources. We estimate that approximately one slight lung injury and one mortality from acoustic stressors could occur in a given year.

We do not anticipate any mortality of this species from vessel strikes.

Death of an individual sea turtle would have a direct fitness consequence to the individual leading to lost reproductive potential that the individual might contribute to the population or sub-population. This lost reproductive potential will vary depending on the sex (male or female) and maturity of the individual. The death of a male would have less of an effect on the population than the loss of a female. Loss of a sexually mature female will have immediate effects on recruitment while lost reproductive potential from mortality of a juvenile female might not be realized for several years.

As stated previously, an average of between 11,000 and 12,700 hawksbill nests are estimated to occur each year in the Pacific. On average hawksbill turtles nest every 2 or 3 years, and lay 4.5 nests each year they (USFWS 2012b). Conservatively assuming that most turtles nest every 2 years and assuming the lower estimate of the number of nests annually, this equates to a likely total population size of approximately 4,889 females (if we assume the turtles nest every 3 years, the total population size is approximately 9,778 females). Removing 1 female from this population in a given year would reduce the reproductive potential of this population by 0.02 percent. We do not consider this to be an appreciable reduction in the numbers of female hawksbill turtles or the reproductive rate of the population, either on an annual basis or continuing into the reasonably foreseeable future. Because we do not expect this level of mortality to result in an appreciable reduction in the numbers or reproductive rate of this population of hawksbill sea turtles, we do not expect this level of mortality to impact the survival or recovery of this population.

The 1998 recovery plan for the U.S. Pacific populations of hawksbill sea turtles identifies increased human presence (primarily thorugh impacts to nesting beaches) and nest predation as the only major threats occurring in Hawaii and sets criteria for the delisting the species. MITT activities are not expected to exacerbate these threats. Delisting requires identifying regional stocks to source beaches; maintenance of stocks above 1,000 nesting females annually; nesting populations at source beaches are stable or increasing for 25 years; maintenance of healthy foraging areas; increases of foraging populations; completion of all priority one tasks; and the finalization of management plans; formal cooperative relationships with revional sea turtle management programs; and international agreements. However, we do not have sufficient information to assign sea turtles killed by Navy activities to individual nesting populations. Because of this, we considered the entire Pacific Ocean population (which is a component of the rangewide, circumglobal, listed entity), and concluded the removal of 1 hawksbill sea turtle in a given year, from acoustic stressors, continuing into the reasonably foreseeable future, is not an appreciable reduction in its numbers or its reproductive capability.

Based on our analysis in this Opinion, we conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of the survival of hawksbill sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of hawksbill sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. That is, acoustic stressors will not have fitness consequences or will not result in an appreciable reduction in reproductive capability at the population or range-wide level. Therefore, we do not anticipate any measurable or detectable reductions in survival rate or trajectory of recovery of the species as listed pursuant to the ESA.

7.1.6.3 Leatherback Sea Turtle

Based on our risk analysis on annual training and testing activities, we conclude that in any given year during the five-year period (August 2015 through August 2020), hawksbill sea turtles could potentially experience take in the form of behavioral harassment resulting from non-impulsive and impulsive acoustic stressors. As described in sections 6.3.6, 6.8.4.4, and 6.8.8.5, potential behavioral responses of sea turtles to anthropogenic sound could include startle reactions, disruption of feeding, disruption of migration, changes in respiration, alteration of swim speed, alteration of swim direction, and area avoidance. Any disruptions are expected to be temporary in nature, with the animal resuming normal behaviors shortly after the exposure. To result in significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no indication this is the case, particularly since foraging habitat would still be available in the environment following the cessation of acoustic exposure. Similarly, we expect temporary disruptions of migration and swim speed or direction to be inconsequential because they can resume these behaviors almost immediately following the cessation of the sound exposure. Further, these sorts of behavioral disruptions may be similar to natural disruptions such those resulting from predator avoidance, or fluctuations in

oceanographic conditions. Therefore, behavioral responses of sea turtles to acoustic stressors are unlikely to lead to fitness consequences and long-term implications for the population.

We anticipate approximately 49 instances of exposure to impulsive acoustic stressors that may result in behavioral harassment. We do not anticipate any additional exposures to non-impulsive acoustic stressors that might result in purely behavioral responses that were not counted as TTS, PTS, or injury. Assuming that the Navy conducts the maximum number of authorized training and testing activities for the maximum number of authorized hours, we estimated 12 takes per year in the form of harassment from TTS resulting from non-impulsive sound stressors. We anticipate zero takes each year during the five-year period in the form of PTS from impulsive sound sources or other forms of injury including GI tract, slight lung injury or mortality from acoustic stressors.

The 1998 recovery plan for the U.S. Pacific populations of leatherback sea turtles does not identify any major threats occurring in the Action Area, but sets criteria for the delisting the species. Delisting requires identifying regional stocks to source beaches, stability in the number of nesting females over 25 years, maintenance of at least 5,000 females in each stock over 6 years, maintenance of healthy foraging habitat, increases of foraging populations, completion of all priority one tasks, and the finalization of management plans. We do not have sufficient information to assign leatherback a specific number of takes from Navy acoustic stressors; however, any leatherbacks affected are not expected to experience fitness consequences because this species does not rely heavily on auditory cues from their environment for breeding, feeding, or sheltering. Because of a lack of fitness consequences and that acoustic stressors are not identified as a threat to leatherback recovery, we do not expect sub-lethal leatherback sea turtle take to impede recovery of this species.

Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the DoD and USCG will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of leatherback sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of leatherback sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. Therefore, we do not anticipate any measurable or detectable reductions in survival rate or trajectory of recovery of sub-populations in the North Pacific or to these species as listed pursuant to the ESA.

7.1.6.4 Loggerhead Sea Turtle

Based on our risk analysis on annual training and testing activities, we conclude that in any given year during the five-year period (August 2015 through August 2020), hawksbill sea turtles could potentially experience take in the form of behavioral harassment resulting from non-impulsive and impulsive acoustic stressors. As described in sections 6.3.6, 6.8.4.4, and 6.8.8.5, potential behavioral responses of sea turtles to anthropogenic sound could include startle reactions,

disruption of feeding, disruption of migration, changes in respiration, alteration of swim speed, alteration of swim direction, and area avoidance. Any disruptions are expected to be temporary in nature, with the animal resuming normal behaviors shortly after the exposure. To result in significant fitness consequences we would have to assume that an individual turtle detects and responds to the acoustic source, and that it could not compensate for lost feeding opportunities by either immediately feeding at another location, by feeding shortly after cessation of acoustic exposure, or by feeding at a later time. There is no indication this is the case, particularly since foraging habitat would still be available in the environment following the cessation of acoustic exposure. Similarly, we expect temporary disruptions of migration and swim speed or direction to be inconsequential because they can resume these behaviors almost immediately following the cessation of the sound exposure. Further, these sorts of behavioral disruptions may be similar to natural disruptions such those resulting from predator avoidance, or fluctuations in oceanographic conditions. Therefore, behavioral responses of sea turtles to acoustic stressors are unlikely to lead to fitness consequences and long-term implications for the population.

We anticipate approximately 54 instances of exposure to impulsive acoustic stressors that may result in behavioral harassment. We do not anticipate any additional exposures to non-impulsive acoustic stressors that might result in purely behavioral responses that were not counted as TTS, PTS, or injury. Assuming that the Navy conducts the maximum number of authorized training and testing activities for the maximum number of authorized hours, we estimated 15 takes per year in the form of harassment from TTS resulting from non-impulsive sound stressors. We anticipate zero takes each year during the five-year period in the form of PTS from impulsive sound sources or other forms of injury including GI tract, slight lung injury or mortality from acoustic stressors.

The North Pacific DPS of loggerhead sea turtles does not have a recovery plan; therefore no recovery criteria have been established, nor have major threats and their remedies specific to loggerhead recovery been established. Any loggerheads affected are not expected to experience fitness consequences because this species does not rely heavily on auditory cues from their environment for breeding, feeding, or sheltering. Because of a lack of fitness consequences and supporting information from a recovery plan suggesting temporary effects from acoustic stressors would impede loggerhead recovery, we do not expect sub-lethal loggerehead sea turtle take to impede recovery of this species.

Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the DoD and USCG will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival or the recovery of loggerhead sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of loggerhead sea turtles in the wild by reducing the reproduction, numbers, or distribution of that species. That is, non-impulsive acoustic stressors will not have fitness consequences at the individual level. Therefore, we do not

anticipate any measurable or detectable reductions in survival rate or trajectory of recovery of sub-populations in the North Pacific or to these species as listed pursuant to the ESA.

7.1.7 Scalloped Hammerhead Shark – Indo-West Pacific DPS

In determining whether U.S. Navy training and testing activities in the MITT Action Area are likely to jeopardize the survival and recovery of the Indo-West Pacific DPS of scalloped hammerhead sharks, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources* and, those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any scalloped hammerhead sharks being exposed to shock waves associated with underwater detonations. Those individuals that are exposed to UNDETs in and around Apra Harbor, Guam would only be so periodically or episodically over certain months or seasons.

In section 6.8, we analyzed the effects of acoustic stressors on scalloped hammerhead sharks. There is no evidence of juvenile or adult injury or mortality resulting from underwater detonations or other impulsive acoustic stressors during Navy training and testing. Additionally, the Navy has mitigation measures in place to reduce the likelihood of this occurring. Therefore we anticipate zero injury or mortality during a given year. We estimated the affected habitat area for a 20 lb. NEW charge to be 99 m^2. In this scenario, any scalloped hammerhead sharks within the 99 m^2 area could be behaviorally-harassed, or up to 99 m^2 of their habitat would be temporarily displaced during each detonation. However, sharks would be expected to return to this habitat soon after each (up to five detonations per day or 20 per week) of the 260 disturbances events and behavioral responses have concluded. We concluded that 260 instances of habitat displacement (each displacing 99 m^2) would not significantly reduce the amount (13,510,249 km^2) of habitat available to the Indo-West Pacific DPS and that scalloped hammerhead sharks would quickly recover from instances of behavioral harassment and TTS within these areas. Therefore, these temporary disruptions of available habitat would not have fitness consequences to individual scalloped hammerhead sharks since they are highly mobile and could find suitable habitat in near proximity to the habitat they were displaced from. We also determined that any instances of temporary hearing loss would not be expected to have fitness consequences to individuals because scalloped hammerheads are long-lived animals and hearing would be expected to return within a short amount of time (hours). Given the nature of testing and training as described above, these periodic or episodic exposure and behavioral response scenarios, including responses to TTS, most often allow sufficient time to return to baseline conditions and resumption of normal behavioral activities such as feeding and breeding. As described previously, including in Section 6.4.7 of this Opinion, the available scientific information does not provide evidence that exposure to acoustic stressors from Navy training and testing activities will impact the fitness of any individuals of this species. Therefore exposure to acoustic stressors will not have population or species level impacts.

The Indo-West Pacific DPS of scalloped hammerhead sharks does not have a recovery plan; therefore, specific downlisting and delisting criteria are not established. We concluded temporary displacement of individuals belonging to this listed entity could occur and that sublethal effects

not rising to the level of injury from acoustic stressors would be temporary and not impact the fitness of individuals or the population.

Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the DoD and USCG will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of the Indo-West Pacific DPS of scalloped hammerhead sharks in the wild by reducing the reproduction, numbers, or distribution of that species. We also conclude that effects from ongoing DoD and USCG training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of the Indo-West Pacific DPS of scalloped hammerhead sharks in the wild by reducing the reproduction, numbers, or distribution of that species. We do not anticipate any reductions in survival rate or trajectory of recovery of the species as listed pursuant to the ESA that would be sufficient to be readily perceived or estimated.

7.1.8 Acropora globiceps

In determining whether U.S. Navy training and testing activities in the MITT Action Area are likely to jeopardize the survival and recovery of *Acropora globiceps*, we assessed effects of the action against the aggregate effects of everything in the *Environmental Baseline* that has led to the current *Status of Listed Resources* and, those effects of future non-Federal activities that are reasonably certain to occur within the Action Area in the reasonably foreseeable future. Many U.S. Navy training exercises and testing activities in the MITT Action Area over a five-year period and continuing into the reasonably foreseeable future will occur without any *Acropora globiceps* colonies being exposed to U.S. Navy vessels, sound fields associated with active sonar pings, or shock waves associated with underwater detonations. Those individuals that are exposed would only be so periodically or episodically.

Based on our analysis on the effects of in-water explosions and direct strike from live and inert ordnance, we determined that mortality of 6.78 m^2 of habitat (which could be approximated to 384 colonies) occupied by live *Acropora globiceps* from Navy explosive ordnance activities around FDM would occur each year. We estimated the area of live *Acropora globiceps* cover around FDM to total 6,322.3 m^2. Therefore, we determined that Navy activities will result in mortality of 0.11 percent of the *Acropora globiceps* reef habitat around FDM each year. In addition to mortality, our analysis estimated 20.34 m^2 of habitat occupied by *Acropora globiceps* will be injured (recoverable injury to approximately 1,152 colonies) from Navy explosive ordnance activities around FDM each year. We also estimated two instances of recoverable injury to *Acropora globiceps* habitat around FDM from ordnance other than high-explosive bombs will occur on an annual basis. Based on coral reef surveys around FDM (DoN 2005a), we estimated 6,322 m^2 of *Acropora globiceps* habitat (roughly equating to 357,800 colonies) may exist around FDM. According to the final listing rule for the species (NMFS 2014, 79 FR 53852) *Acropora globiceps*' rangewide abundance is at least tens of millions of colonies at the time of listing. Using this information and our assumption on average colony size, we estimate that there is likely more than 176,700m^2 of live *Acropora globiceps* cover (roughly 10 million colonies)

rangewide. The estimated annual mortality of live coral cover (6.78 m^2) assumed to be occupied by *Acropora globiceps* (approximately 384 colonies) around FDM is roughly 0.1 percent of available habitat assumed to be occupied by *Acropora globiceps* around FDM and and no more than 0.004 percent of the habitat occupied by *Acropora globiceps* range-wide. The mortality of *Acropora globiceps* embryos and larvae around FDM potentially occurring from in-water explosions of HE-bombs that miss their targets on FDM is expected to be minimal. Additionally, explosions would need to occur when larvae are present and would not represent a significant increase in natural mortality of larvae which can be up to 90 percent annually. This level of mortality from explosives around FDM is expected to have negligible impacts to growth and recruitment of *Acropora globiceps* at the population and rangewide scale.

Injuries could include varying degrees of abrasion, breakage, and/or pieces of debris settling upon portions of the coral colony. However, because only a portion of the coral colony polyps would be affected, we do not expect injuries to result in coral colony mortality. Uninjured coral polyps within the colony affected would be able to sustain the "individual" as defined in Section 6.5. The tissue thickness of *Acropora* species is 1 to 2 mm thick, considerably thinner than many coral species, which allows them to grow quicker than many other species (Loya et al. 2001). Therefore, injured *Acropora globiceps* colonies would likely be able to bud and develop new polyps to replace those lost in the injury. Fragmentation may also occur where pieces of the coral colony break off, separating a single colony into two or more individuals. Fragmentation may lead to a large number of asexually-produced, genetically identical colonies, commonly resulting in a population made up of more asexually-produced colonies than sexually-produced colonies (Hughes 1984). Injuries to portions of colonies are also not expected to substantially impact coral gamete production. As described in Section 4.2.11.3, the reproductive biology of *Acropora globiceps*, and other coral species, results in prolific larval production and high natural mortality from a combination of factors including predation and dispersal to areas within the ocean without appropriate settlement habitat (e.g., deeper or colder water, unsuitable substrate). Therefore, a temporary decrease in the number of gamete producing coral polyps within a coral colony is expected to result in a negligible decrease in the overall number of gametes produced by the colony and population of *Acropora globiceps* around FDM. Because we do not expect temporary injuries to last for substantial durations and we do not expect these injuries to result in lost reproductive potential, we do not expect injuries to result in fitness consequences to individual colonies or the populations they represent.These conclusions are further supported by coral reef surveys that have been conducted around FDM in the recent past. U.S. military training has been occurring in the MITT Action Area for many years and, although injury and mortality of *Acropora globiceps* in these areas has likely occurred from this historical activity, reefs in these areas continue to survive and reproduce. A 2013 report presented the findings of the calender year 2012 U.S. Navy coral reef survey and compares findings from those of the previous 12 surveys (Smith et al. 2013). The report indicates that despite ongoing use by the Department of Defense as a live and inert range, no significant impacts to the physical or biological environment were detected between 1999 and 2012. We acknowledge our estimation of effects on ESA-listed corals for activities around FDM is based on limited observations on the effects of in-water explosions of military ordnance, but it provides a reasonable estimate of what could be expected in a given year or over the reasonably foreseeable future and that most impacts to *Acropora globiceps* colonies would often be temporary and recoverable.

Acropora globiceps does not have a recovery plan; therefore, specific downlisting and delisting criteria are not established. We concluded mortality of this species will likely occur. Considering the total available reef habitat around FDM and range-wide for the species and estimated instance of mortality, we conclude that the mortality of 6.78 m^2, and injury to 20.34 m^2, of live *Acropora globiceps* would not be an appreciable reduction in survival or recovery of the species. Additionally, the extent of mortality of embryonic and larval life stages of *Acropora globiceps* prior to settling would be insignificant to the overall recruitment potential for individual colonies or the population.

As described in the *Status of Listed Resources* and *Environmental Baseline* sections of this Opinion, one of the primary anthropogenic threats to reef-building corals, including *Acropora globiceps*, is climate change induced ocean warming. This threat is expected to continue into the future. However, the proposed action will not worsen this threat and it will not lessen the species' traits that mitigate its extinction risk, including its abundance and life history characteristics (e.g., resilience to bleaching events, reproductive strategy). Based on the evidence available, including the *Environmental Baseline* and *Cumulative Effects*, stressors resulting from training and testing activities the Navy will conduct in the MITT Action Area on an annual basis, cumulatively over the five year period from August 2015 through August 2020, or cumulatively for the reasonably foreseeable future (assuming there are no significant changes to the *Status of Listed Resources* or *Environmental Baseline*), would not be expected to appreciably reduce the likelihood of the survival of *Acropora globiceps* in the wild by appreciably reducing the reproduction, numbers, or distribution of that species. While a small number of individual colonies would be killed each year around FDM, this number is likely replaced with new polyps in the population a rate greater than is lost in a given year from Navy activities and continuing into the reasonably foreseeable future. Instances of recoverable injury such as breakage resulting from these stressors may also serve to propagate coral colonies in and around areas where mortality is estimated. In our analysis, we also assumed that *Acropora globiceps* would be present in all instances of detonations and impacts from military expended materials. We acknowledge that this is likely an overestimate of actual distribution and level of effects. We also conclude that effects from ongoing Navy training and testing activities continuing into the reasonably foreseeable future would not be expected, directly or indirectly, to appreciably reduce the likelihood of recovery of *Acropora globiceps* in the wild by reducing the reproduction, numbers, or distribution of that coral species.

8 CONCLUSION

During the consultation, we reviewed the current status of endangered blue whales, fin whales, humpback whales, sei whales, and sperm whales, threatened green sea turtles, endangered hawksbill sea turtles, endangered leatherback sea turtles, endangered loggerhead sea turtles, endangered olive ridley sea turtles, the threatened Indo-West Pacific DPS of scalloped hammerhead sharks, and threatened *Acropora globiceps*. We also assessed the status of the proposed endangered Central West Pacific DPS of green sea turtle and threatened Central North Pacific DPS of humpback whale as part of our conference report. We also assessed the *Environmental Baseline* for the MITT Action Area including ongoing DoD and USCG training and testing in the MITT Action Area along with the potential effects of DoD and USCG

proposed Mariana Islands Training and Testing Study from August 2015 through August 2020 along with the National Marine Fisheries Service's Permit Division's proposed rule on the take of marine mammals incidental to training and testing activities and proposed letter of authorization for the five-year period.

We conclude that Navy training and testing activities in the MITT Action Area and NMFS' issuance of the MMPA regulations and LOA are likely to adversely affect but will not appreciably reduce the ability of these threatened and endangered species under NMFS' jurisdiction to survive and recover in the wild. Therefore, we conclude that these activities are not likely to jeopardize the continued existence of any endangered or threatened species. The actions also will not result in the destruction or adverse modification of critical habitat during the five-year period of the MMPA rule or continuing into the reasonably foreseeable future. These conclusions will remain valid assuming that the type, amount and extent of training and testing do not exceed levels assessed in this opinion and/or the status of the species affected by these actions does not change significantly from that assessed in this Opinion.

9 INCIDENTAL TAKE STATEMENT

Section 9 of the ESA prohibits the take of endangered species without special exemption. ESA § 9 statutory prohibitions are limited to "endangered" species unless extended to "threatened" species. In the case of threatened species, section 4(d) of the ESA leaves it to the Secretary's discretion whether and to what extent to extend the statutory 9(a) ''take'' prohibitions, and directs the agency to issue regulations it considers necessary and advisable for the conservation of the species. At the time of this consultation, take prohibitions have not been extended to the threatened Indo-Pacific DPS of scalloped hammerhead shark or the threatened species of Indo-Pacific corals, including *Acropora globiceps*. However, consistent with *CBD v. Salazar*, 695 F.3d 893 (9th Cir. 2012), we assessed the amount or extent of take to these threatened species that is anticipated incidental to Navy training and testing activities and include this information in the ITS. Inclusion of these species in the incidental take statement serves to assist the Action Agency with monitoring of take and provides a trigger for reinitiation if levels of estimated take are exceeded.

Take is defined as to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture or collect, or to attempt to engage in any such conduct. Harm is further defined by NMFS to include significant habitat modification or degradation that results in death or injury to listed species by significantly impairing essential behavioral patterns, including breeding, feeding, or sheltering. Incidental take is defined as take that is incidental to, and not the purpose of, the carrying out of an otherwise lawful activity. Under the Marine Mammal Protection Act, there is a definition of what is referred to as Level B harassment: "any act of pursuit, torment, or annoyance which... has the potential to disturb a marine mammal or marine mammal stock in the wild by causing disruption of behavioral patterns, including, but not limited to, migration, breathing, nursing, breeding, feeding, or sheltering but which does not have the potential to injure a marine mammal or marine mammal stock in the wild" 16 U.S.C. §1362(18)(A)(ii). For this consultation, we interpret "harass" using the MMPA definition to marine mammals. For other species, specifically sea turtles, we apply "harass" to mean an intentional or negligent action that has the potential to

injure an animal or disrupt its normal behavior to a point where such behaviors are abandoned or significantly altered. Section 7(b)(4) and section 7(o)(2) provide that taking that is incidental to an otherwise lawful agency action is not considered to be prohibited taking under the ESA if that action is performed in compliance with the terms and conditions of this incidental take statement.

9.1 Amount or Extent of Take

The section 7 regulations require NMFS to specify the impact of any incidental take of endangered or threatened species; that is, the amount or extent, of such incidental taking on the species (50 CFR §402.14(i)(1)(i)). The amount of take represents the number of individuals that are expected to be taken by proposed actions while the extent of take or "the extent of land or marine area that may be affected by an action" if we cannot assign numerical limits for animals that could be incidentally taken during the course of an action (51 FR 19953). The amount of take resulting from the Navy's activities was estimated based on the best information available.

9.1.1 Take Incidental to Mariana Islands Training and Testing Activities and Issuance of the MMPA Rule and Letters of Authorization

In the following sections we summarize the anticipated take from annual training and testing activities by species as proposed by the Navy and the interrelated and interdependent actions of issuance of a five-year regulation and LOAs by NMFS' Permits Division to authorize take of marine mammals pursuant to the MMPA.

Section 7(b)(4)(C) of the ESA provides that if an endangered or threatened marine mammal is involved, the taking must first be authorized by Section 101(a)(5) of the MMPA. Accordingly, the terms of this incidental take statement and the exemption from Section 9 of the ESA become effective only upon the issuance of MMPA authorization (i.e., five year regulations and LOA) to take the marine mammals identified here. Absent such authorization, this statement is inoperative for marine mammals.

Table 69 provides the anticipated take incidental to training and testing activities in a given year where all possible activities are carried out in that year.

Table 69. Take Authorized Incidental to Training and Testing Activities, Issuance of the MMPA Regulation and Issuance of the LOA

ESA-Listed Species	Impulsive and Non-Impulsive Acoustic Stressors				Military Expended Material (Inert Munitions) and Detonations (Live Munitions)	Vessel Strike
	Behavioral Harassment	Harm (PTS)	Harm (Slight Lung Injury)	Mortality	Injury / Mortality	Mortality
Cetaceans (Mysticetes)						
Blue Whale	**28 (25)/yr** [3]	0	0	0	-	-
Fin Whale	**28 (24)/yr** [3]	0	0	0	-	-
Humpback Whale – Range-wide[1]	**860 (679)/yr** [3]	0	0	0	-	-
Humpback Whale – Western North Pacific DPS[1]	**860 (679)/yr** [3]	0	0	0	-	-
Sei Whale	**319 (258)/yr** [3]	0	0	0	-	-
Cetaceans (Odontocetes)						
Sperm Whale	**506 (54)/yr** [3]	0	0	0	-	-
Sea Turtles						
Green Turtle – Range-wide[2]	**2,099 (262)/yr** [3]	**1/yr**	**3/yr**	**1/yr**	**-**	**1/yr**
Green Turtle – Central West Pacific DPS[2]	**2,099 (262)/yr** [3]	**1/yr**	**3/yr**	**1/yr**	**-**	**1/yr**
Hawksbill Turtle	**149 (20)/yr** [3]	0	**1/yr**	**1/yr**	**-**	**-**
Leatherback Turtle	**61 (12)/yr** [3]	0	0	0	-	-
Loggerhead Turtle – North Pacific DPS	**69 (15)/yr** [3]	0	0	0	-	-

Fish						
Scalloped Hammerhead Shark – Indo-West Pacific DPS	**Temporary effects to 99 m^2 of available habitat no more than 260 times per year (No more than 5 times per day or 20 times per week at all sites)[4]**	-	-	**0/yr[5]**	-	-
Invertebrates (Corals)						
*Acropora globiceps**	-	-	-	-	**Mortality and injury of reef area around Farrallon de Medinilla up to 6.78 m^2 and 20.24 m^2, respectively, from HE bombs, annually and continuing into the reasonably foreseeable future.[6] Additionally, two (2) instances of reef area injury around FDM annually continuing into the reasonably foreseeable future from ordnance other than HE bombs.**	-

[1]During this consultation, NMFS proposed to divide the globally listed endangered species (humpack whale) into 14 DPSs and to remove the species-level listing, and in its place list two DPSs and endangered and two DPSs as threatened. If the proposed rulemaking becomes effective and if the proposed listings are finalized as proposed and assessed in this Opinion, incidental take estimates for the range-wide species will become null and void and the estimated incidental take for the Western North Pacific DPS will take effect.

[2] During this consultation, NMFS proposed to redesignate the breeding populations of green sea turtles in Florida and the Pacific coast of Mexico (currently listed as endangered); and elsewhere currently listed as threatened. NMFS proposed eight threatened DPSs and three endangered DPSs. Green turtles in the MITT Action Area would occur in the proposed endangered Central West Pacific DPS. If the proposed rulemaking becomes effective and if the proposed listings are finalized as proposed and as assessed in this Opinion, incidental take estimates for the range-wide threatened species will become null and void and the estimated incidental take for the Central West Pacific DPS will take effect.

[3]The subset of estimated instances of TTS as a subset of the total instances of behavioral harassment are provided in parenthesis.

[4]The estimated extent of take is provided in terms of a habitat surrogate (i.e., area of affected habitat) for behavioral harassment. Reinitation will be required if (1) effects to scalloped hammerhead sharks attributable to UNDET activities exceed temporary behavioral effects or temporary habitat displacement, (2) effects to scalloped hammerhead sharks attributable to UNDET activities occur beyond 99m^2 from the detonation location, or (3) more than 260 explosive detonations at Apra Harbor, Agat Bay, and Piti Point occur in a year (not to exceed five detonations in a day and not to exceed 20 detonations in a week).

[5]In the absence of any empirical data that mortality has resulted from Navy training and testing, we anticipate zero mortalities; however, if a single mortality is observed, reinitiation of consultation would be required.

[6]The estimated extent of take is provided in terms of an ecological surrogate (i.e., coral habitat area). Reinitiation will be required if the Navy: (1) exceeds a one percent miss rate when the total number of expended HE bombs in Table 66 is reached, or (2) exceeds the number of items expended by type in Table 66 in a given year. In either scenario, the estimated area of coral habitat impacted (injury and mortality) could be exceeded and reinitiation would be required.

- Either exposures to the stressor are not expected or responses to exposures rising to the level of "take" are not expected.

9.2 Effects of the Take

In the accompanying biological opinion, we determined that the anticipated take levels specified above are not likely to result in jeopardy to any of the affected species or destruction or adverse modification of critical habitat that has been designated for such species.

9.3 Reasonable and Prudent Measures

The following reasonable and prudent measures are necessary and appropriate to minimize impacts of incidental take of the species listed in Table 69 in the incidental take statement of this biological opinion.

1. The Navy and NMFS' Permits Division shall have measures in place to limit the potential for interactions with ESA-listed species that may rise to the level of take as a result of the proposed actions described in this Opinion. Standards and procedures should be incorporated into policy and guidance, directives, and standard operating procedures as appropriate.

2. The Navy and NMFS' Permits Division shall report all observed interactions resulting in take with any ESA-listed species (marine mammals, fish, adult corals (reefs, etc.) and sea turtles) resulting from the proposed actions that are observed during the course of Navy training and testing activities and while implementing monitoring requirements for marine mammals as required by the LOA.

3. The Navy shall monitor effects to coral reef habitat at FDM.

9.3.1 Monitoring

As discussed in Section 9.1 of this Opinion, the estimated take of ESA-listed sea turtles and marine mammals from acoustic stressors is based on Navy modeling, which represents the best available means of numerically quantifying take. As the level of non-impulsive or impulsive acoustic activities increases, the level of take is likely to increase as well. For non-lethal take from acoustic sources specified above, feasible monitoring techniques for detecting and calculating actual take of marine mammals and sea turtles at the scale of MITT activities do not exist. We are not aware of any other feasible or available means of determining when estimated take levels may be exceeded. Therefore, we must rely on Navy modeling (for marine mammals and sea turtles), and the link between sonar or explosive use and the level of take, to determine when anticipated take levels have been exceeded.

The take levels specified above also include one annual mortality each for green and hawksbill sea turtles from acoustic sources (based on Navy modeling) and one annual green sea turtle mortality resulting from a vessel strike. It is very difficult to detect the occurrence of a vessel strike involving a sea turtle. Even with regional stranding network data, it is exceedingly difficult to attribute injury or mortality to Navy training or testing activities given multiple use of harbors, coastal zones, and offshore areas by Navy and non-Navy entities. Although we believe that Navy monitoring may detect some, sea turtle mortalities most likely go undetected. Therefore, for these forms of take as well, we must again rely on estimated take associated with levels of activities and any opportunistic observations of sea turtle mortalities during or following testing or training activities as measurements of take and a trigger for reinitiation of consultation. We

are aware of no other feasible or available alternative means of determining when estimated levels of these forms of take are exceeded.

The amount of anticipated take of the Indo-West Pacific DPS of scalloped hammerhead sharks and *Acropora globiceps* from acoustic stressors and military expended materials (*Acropora globiceps*) are expressed as habitat surrogates, consistent with 50 C.F.R. § 402.14(i).

The Navy is required under the final MMPA rule and the reasonable and prudent measures in this Opinion to report activity levels (including sonar hours and the type and number of explosives used) to NMFS. As such, we established a term and condition of this Incidental Take Statement, requiring the Navy to report to NMFS any exceedance of activity levels or planned testing or training events specified above and in the final MMPA rule before the exceedance occurs (if operational security considerations allow), or as soon as operational security considerations allow after the relevant activity is conducted. Exceedance of an activity level will require the Navy to reinitiate consultation.

Reinitiation of consultation shall also be required if Navy monitoring programs detect any unanticipated form of take of ESA-listed species not specified above.

9.3.2 Reporting

The Navy and NMFS' Permits and Conservation Division shall submit reports that identify the general location, timing, number of sonar hours and other aspects of the training exercises and testing activities, and any potential to exceed levels of training and testing analyzed in this Opinion they conduct in the MITT Action Area over the five year period of the MMPA regulations and letters of authorization to help assess the actual amount or extent of take incidental to training and testing activities.

The Navy shall also submit annual reports on the levels and types of ordnance used at FDM that impacts coral reef habitat, and shall provide summary reports for required coral surveys to the ESA Interagency Cooperation Division upon completion but not less than once every five years.

9.4 Terms and Conditions

In order to be exempt from the prohibitions of section 9 of the ESA, the Navy (as Executive Agent for DoD and USCG activities) and NMFS' Permits Division must comply with the following terms and conditions, which implement the reasonable and prudent measures described above and outline required reporting and monitoring requirements. These terms and conditions are nondiscretionary:

1. To satisfy the reasonable and prudent measures above, the Navy must report to NMFS any exceedance of activity levels (e.g. sonar hours and the type and numbers of explosives used) of planned testing or training events specified in the preceding Opinion and in the final MMPA rule before the exceedance occurs (if operational security considerations allow), or as soon as operational security considerations allow after the relevant activity is conducted. Exceedance of an activity level will require the Navy to reinitiate consultation.

2. To satisfy reasonable and prudent measure number one in Section 9.3, the Navy shall implement all mitigation and monitoring measures as proposed in the action described in the final EIS/OEIS and consultation initiation package, as specified in the final MMPA rule and LOAs, and as described in this Opinion in Section 2.9.

3. To satisfy reasonable and prudent measure number two in Section 9.3, the Navy shall immediately (or as soon as operational security considerations allow) notify NMFS if a dead or seriously injured sea turtle is observed during Navy testing or training activities that is potentially attributable to these activities, including but not limited to the use of explosives and vessel strike. If the Navy observes one or more dead or seriously injured sea turtles in each of two consecutive years during Navy testing and training activities that is potentially attributable to these activities, the Navy shall contact NMFS to determine if reinitiation is required.

4. To satisfy reasonable and prudent measure number three in Section 9.3, the Navy shall monitor and report annual numbers of ordnance by type (e.g., Bomb HE, Bomb NEPM, Projectiles, Missiles, Rockets, etc.) expended at FDM. Navy will report all observed ricochets and misses that land in waters surrounding FDM occupied by corals. Additionally, the Navy shall provide reports of any observed in-water effects (e.g., crater size, observed mortality) to corals resulting from detonations of high-explosive bombs as they are discovered incidental to routine operations or during coral reef surveys to confirm or to help revise assumptions on the effects of high-explosive bombs to corals at various depths.

5. To satisfy reasonable and prudent measure number three in Section 9.3, the Navy shall compile existing baseline information and then, no less than once every five years, shall survey coral reef habitat around FDM within 20 meters of water depth. These surveys shall be structured to confirm presence or absence and abundance of ESA-listed corals and to assess general trends in coral reef species composition, percent coral coverage, and condition (disease, predators, extent of breakage, etc.).

6. To satisfy reasonable and prudent measures number one and two in Section 9.3, NMFS' Permits Division shall ensure that all mitigation and monitoring measures as proposed by the Navy and as proposed by NMFS in the final MMPA rule and in Section 2.9 of this Opinion are implemented by the U.S. Navy through the issuance of a final rule and subsequent letters of authorization (LOA) pursuant to the MMPA.

7. To satisfy reasonable and prudent measures number one and two in Section 9.3, the Navy as the Executive Agent for DoD and USCG activities, shall coordinate the execution of these required actions with other affected military services and the USCG and shall compile and summarize any and all annual monitoring and exercise reports and describe observed interactions with ESA-listed species [marine mammals, fish, adult corals (reefs, etc.) and sea turtles] that involve their actions.

8. To satisfy reasonable and prudent measures number one and two in Section 9.3, the Navy shall annually request sea turtle stranding data from the regional NMFS stranding office

and will review any data provided by the regional office to determine if any unusual stranding events or increases in stranding rates may be attributed to Navy training and testing. If the Navy identifies an increase in sea turtle stranding data potentially associated with Navy training and testing activities, the Navy shall contact NMFS to determine if reinitiation is required.

10 CONSERVATION RECOMMENDATIONS

Section 7(a)(1) of the ESA directs Federal agencies including the U.S. Navy, U.S. Air Force, U.S. Coast Guard and NMFS to utilize their authority to further the purposes of the ESA by carrying out conservation programs for the benefit of endangered and threatened species. Conservation recommendations are discretionary agency activities to minimize or avoid adverse effects of a proposed action on listed species or critical habitat to help implement recovery plans or to develop information.

1. Monitor sighting, location, and stranding data for ESA-listed marine mammals, sea turtle species, scalloped hammerhead shark, and adult corals in the MITT Action Area.

2. As practicable, develop procedures to aid any individuals of an ESA-listed marine mammals, sea turtle species, scalloped hammerhead shark, and adult corals that have been impacted by DoD and USCG training and testing activities and is in a condition requiring assistance to increase likelihood of survival.

3. Continue to model potential impacts to ESA-listed species using NAEMO and other relevant models; validate assumptions used in risk analyses; and seek new information and higher quality data for use in such efforts.

4. Continue technical assistance/adaptive management efforts with NMFS to help inform future consultations on DoD and USCG training and testing in the MITT Action Area.

5. The Navy should coordinate with NMFS to monitor for presence of ESA-listed corals in and around the Piti Point Mine Neutralization site and Underwater Detonation Sites within Apra Harbor, Guam to ensure the absence of these species and to avoid interactions.

6. The Navy should coordinate with NMFS to understand scalloped hammerhead shark abundance and density estimates for the MITT Action Area.

7. The Navy should explore methods to better quantify behavioral take of sea turtles not rising to the level of TTS.

8. The Navy should explore methods to better quantify the risk of vessel strike to sea turtles.

In order for NMFS to be kept informed of actions minimizing or avoiding adverse effects or benefitting listed species or their habitats, NMFS requests notification of the implementation of any conservation recommendations.

11 REINITIATION OF CONSULTATION

This concludes formal consultation on proposed Mariana Islands Training and Testing activities the DoD and USCG will conduct from August 2015 through August 2020. As provided in 50 CFR §402.16, reinitiation of formal consultation is required where discretionary Federal agency involvement or control over the action has been retained (or is authorized by law) and if: (1) the amount or extent of incidental take is exceeded; (2) new information reveals effects of the agency action that may affect listed species or critical habitat in a manner or to an extent not considered in this opinion; (3) the agency action is subsequently modified in a manner that causes an effect to the listed species or critical habitat not considered in this opinion; or (4) a new species is listed or critical habitat designated that may be affected by the action. In instances where the amount or extent of incidental take is exceeded, the U.S. Navy and NMFS' Permits Division must contact the ESA Interagency Cooperation Division, Office of Protected Resources immediately.

12 INFORMATION QUALITY ACT

Section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Public Law 106-554, AKA the Data Quality Act or Information Quality Act) directed the Office of Management and Budget (OMB) to issue government-wide guidelines that "provide policy and procedural guidance to federal agencies for ensuring and maximizing the quality, objectivity, utility, and integrity of information (including statistical information) disseminated by federal agencies." OMB complied by issuing guidelines which direct each federal agency to 1) issue its own guidelines; 2) establish administrative mechanisms allowing affected persons to seek and obtain correction of information that does not comply with the OMB 515 Guidelines or the agency guidelines; and 3) report periodically to OMB on the number and nature of complaints received by the agency and how the complaints were handled. The OMB Guidelines can be found at:

http://www.whitehouse.gov/omb/fedreg/reproducible2.pdf

The Department of Commerce Guidelines can be found at:
http://ocio.os.doc.gov/ITPolicyandPrograms/Information_Quality/index.htm

The NOAA Section 515 Information Quality Guidelines, created with input and reviews from each of the components of NOAA Fisheries, went into effect on October 1, 2002. The NOAA Information Quality Guidelines are posted on the NOAA Office of the Chief Information Officer Webpage. http://www.cio.noaa.gov/Policy_Programs/info_quality.html

Subject: Mariana Islands Training and Testing Program

This document transmits the U.S. Fish and Wildlife Service's (Service) Biological Opinion (Opinion) addressing the subject action as proposed by the Department of the Navy (Navy). The Navy is serving as the lead Federal agency for implementation of Department of Defense (DoD) readiness training under the Mariana Islands Training and Testing (MITT) program. At issue are the effects of the proposed action on the threatened Mariana fruit bat (*Pteropus mariannus mariannus*) and the endangered Micronesian megapode (*Megapodius laperouse*). The enclosed Opinion was prepared in accordance with the requirements of section 7 of the Endangered Species Act (ESA) of 1973 as amended (16 U.S.C. 1531 et seq.). The Service initiated formal consultation on the proposed MITT program on August 4, 2014 (Service 2014a).

This Opinion is based primarily on information provided in: (1) the Navy's Biological Assessment (BA) for the MITT program, dated August 2014, as amended (Navy 2014a,b); (2) the Service's Opinion addressing the U.S. Air Force's (USAF) Intelligence, Surveillance, Reconnaissance, and Strike Capability (ISR Strike) project (Service 2006a); (3) the Service's Opinion on the Mariana Islands Range Complex (MIRC) program (Service 2010a), as amended (Service 2013a, 2014a), on which the MITT program is based; and (4) other sources of information cited herein. A complete decision record for this consultation is on file at the Service's Pacific Islands Fish and Wildlife Office (PIFWO).

This Opinion also serves as the ESA section 7 compliance document for the proposed MITT program for the Navy, USAF, U.S. Army, U.S. Coast Guard, and the U.S. Marine Corps.

CONSULTATION HISTORY

On October 3, 2006, the Service issued an Opinion to the USAF addressing the ISR Strike action. The conservation measures included in the proposed action subsequently became a component of the MIRC program. That Opinion (Service 2006a) is herein incorporated by reference.

On February 22, 2010, the Service issued an Opinion to the Navy addressing the MIRC program. That Opinion (Service 2010a) and amendments to that Opinion dated June 27, 2013 and June 11, 2014 are herein incorporated by reference (Service 2013a, 2014a).

On April 3, 2014, the Navy transmitted a letter requesting the reinitiation of formal consultation and the BA for the MITT program, formerly identified as the MIRC program.

On May 9, 2014, the Service determined that the information in the BA was insufficient to initiate the consultation and requested additional information from the Navy on the MITT program.

On June 19, 2014, the Navy transmitted an addendum to the BA for the MITT program (Navy 2014b) in response to the Service's May 9, 2014, request.

On August 7, 2014, the Service formally advised the Navy that formal consultation had been initiated on the proposed MITT program.

On October 31, 2014, the Navy informally amended (via email) the BA for the MITT program based on discussions with the Service during October of 2014. The Navy and the Service corresponded by email on multiple occasions during November of 2014 to clarify aspects of the proposed MITT program and the findings presented in the BA.

On November 6, 2014, the Navy confirmed via an email to the Service that the Navy had made "no effect" determinations relative to the proposed MITT program for the following listed species and critical habitats: the endangered hayun lagu (*Serianthes nelsonii*), *Osmoxylon mariannense*, *Nesogenes rotensis*, Guam Micronesian kingfisher (*Todirhamphus c. cinnamominus*), Guam rail (*Gallirallus owstoni*), short-tailed albatross (*Phoebastria albatrus*), Hawaiian petrel (*Pterodroma sandwichensis*), and Rota bridled white-eye (*Zosterops rotensis*), the threatened Newell's shearwater (*Puffinus auricularis newelli*), Rota bridled white-eye critical habitat on Rota, Mariana crow critical habitat on Guam and Rota, Mariana fruit bat critical habitat on Guam, and Guam Micronesian kingfisher critical habitat on Guam.

On December 18, 2014, the Service provided a draft of this Opinion to the Navy for review and comment.

On January 9, 2015, the Service received comments from the Navy on the draft Opinion.

On January 22, 2015, the Navy provided a comprehensive list of conservation measures for the MITT program. The Navy also provided clarification regarding sea turtle conservation measures that were previously agreed to by the Navy in December 2014.

On February 20, 2015, the Navy provided a final revised list of conservation measures for the MITT program.

On February 20, 2015, the Service formally advised the Navy that we concur with the determinations in the BA that the proposed MITT program is not likely to adversely affect the threatened green sea turtle (*Chelonia mydas*), endangered hawksbill turtle (*Eretmochelys*

imbricate), endangered nightingale reed-warbler (*Acrocephalus luscinia*), endangered Mariana crow (*Corvus kubaryi*), endangered Mariana swiftlet (*Aerodramus bartschi*), and the endangered Mariana common moorhen (*Gallinula chloropus guami*).

DESCRIPTION OF THE PROPOSED ACTION

As noted above, the proposed MITT program is an amendment of the MIRC program currently being carried out by the Navy, U.S. Air Force, U.S. Army, U.S. Coast Guard, and the U.S. Marine Corps on Guam, Rota, Tinian, Saipan, and Farallon de Medinilla (FDM). The Navy continues to be the designated lead Federal action agency for purposes of conducting ESA consultation on this action. The BA for the MITT program is herein incorporated by reference and includes a detailed description of the proposed action. In general, the proposed MITT program involves strike warfare and use of FDM, amphibious warfare on Guam and Tinian, Naval special warfare on Guam, Rota, Tinian, Saipan, and FDM, and other activities described below; see also Table 1-1 in the BA.

According to the BA, the types of proposed training activities under the MITT program are the same as those being implemented under the MIRC program, but with increases in the number of training activities that would occur within the Action Area. In particular, the "…cumulative net explosive weight (NEW) for munitions use on FDM would increase…" under the proposed MITT program.

According to the addendum to the BA, as proposed, the MITT program would be implemented into the "reasonable foreseeable future", which has been interpreted by the Service to mean an indefinite period of time within the context of our analysis. In addition, the BA includes the following increases in training activities compared to levels currently being implemented under the MIRC program:

Strike Warfare and Use of FDM. The number of activities, the amount of ordnance, and the use of rockets would increase on FDM. The increase in activities pertains to bombing, gunnery, and missile exercises. The increase in activities will result in a higher NEW being expended, as measured cumulatively over the course of a year.

Amphibious Warfare on Guam and Tinian. The number of amphibious warfare training activities, amphibious assaults, amphibious raids, and urban warfare training and noncombatant evacuation actions would increase on Guam and Tinian.

Naval Special Warfare on Guam, Rota, Tinian, Saipan, and FDM. Within these four islands, there would be an increase in personnel insertion/extraction, parachute insertion, direct action (combat close quarters), direct action (breaching), and tactical (air control party) training activities as well as humanitarian assistance/disaster relief operations. Firing exercises that target the Naval Surface Fire Support targets (i.e., cliff targets on FDM) are also included under the MITT program.

Naval special warfare activities that do not change relative to those currently being implemented under the MIRC program include intelligence, surveillance, and reconnaissance activities as well as embassy reinforcement exercises. These activities primarily occur on Guam, but Rota, Tinian,

and Saipan may also be used. Military training based out of the Rota International Airport for combat search and rescue currently being implemented under the MIRC program would not change under the MITT program.

Other Activities. Under the MITT program, water purification activities are proposed. All other training activities currently being implemented under the MIRC program relative to convoy and navigation maneuvers, field training exercises, force protection, anti-terrorism, seize airfield, airfield expeditionary, and land demolitions would continue under the MITT program.

The proposed increases in the frequency of the above training activities are discussed in detail in Appendix A of this Opinion.

Conservation Measures for ESA-listed Species. In response to a request from the Service during this consultation, the Navy provided (via email) the Table in Appendix B characterizing the current conservation measures being implemented under the MIRC program and those proposed under the MITT program. Included are specific measures for brown treesnake (BTS) control and interdiction, specific measures to avoid and minimize invasive species transport and introduction, and specific measures to provide for a rapid response to such introductions. These conservation measures are incorporated into the proposed action. These measures are also detailed in the Effects of the Action section, below.

Term of the Proposed Action. As discussed above and in the addendum to the BA (Navy 2014b), and recognizing that DoD requirements change overtime in response to global or geopolitical events and other factors, the activities addressed by this consultation are expected to continue into the reasonably foreseeable future, along with associated impacts. This timeframe is generally assumed to be no less than 5 years, but for purposes of this consultation, we interpret to mean the proposed activities, and associated adverse effects to the listed species, may continue into the future for an indefinite period of time.

DESCRIPTION OF THE ACTION AREA

The term "action area" is defined in the implementing regulations for section 7 at 50 CFR 402.02 as "all areas to be affected directly or indirectly by the Federal action and not merely the immediate area involved in the action."

The action area for this consultation includes portions of Guam, Rota, Tinian, and Saipan, plus the entire island of FDM. The specific areas likely to be affected, directly or indirectly, by the proposed action are discussed in detail in the BA.

ANALYTICAL FRAMEWORK FOR THE JEOPARDY DETERMINATION

The analysis in the following sections relies on four components to support the jeopardy determination for each of the listed species considered herein: (1) the *Status of the Species*, which evaluates the species' range-wide condition, the factors responsible for that condition, and its survival and recovery needs; (2) the *Environmental Baseline*, which evaluates the condition of the species in the action area, the factors responsible for that condition, and the relationship of

the action area to the survival and recovery of the species rangewide; (3) the *Effects of the Action*, which determines the direct and indirect impacts of the proposed Federal action and the effects of any interrelated or interdependent activities on the species; and (4) *Cumulative Effects*, which evaluates the effects of future, non-Federal activities in the action area on the species.

In accordance with the implementing regulations for section 7 and Service policy, the jeopardy determination is made in the following manner: the effects of the proposed Federal action are evaluated in the context of the aggregate effects of all factors that have contributed to the species' current status and, for non-Federal activities in the action area, those actions likely to affect the species in the future, to determine if implementation of the proposed action is likely to cause an appreciable reduction in the likelihood of both the survival and recovery of the species in the wild.

STATUS OF THE SPECIES

Micronesian Megapode

The Micronesian megapode, once referred to as LaPerouse's megapode, was federally listed as endangered in 1970 (Service 1970, p. 8,496). No critical habitat has been designated for this species. The recovery plan for the Micronesian megapode was finalized in 1998 (Service 1998, pp. 62). The most recent five-year status review addressing the megapode was completed in 2010 (Service 2010b).

The Micronesian megapode is endemic to Guam, the Commonwealth of the Northern Mariana Islands (CNMI), and Palau. Populations on Guam and Rota are considered extirpated (Service 1998, p. 3; Stinson 1992, p. 220; Amidon and Kessler, 2009; pers. comm.). The megapode population on Anatahan was thought to have been extirpated after the 2003 Anatahan eruption, but have recolonized since (Kessler 2006, p. 3; Kessler 2009, pers. comm.; Amidon et al. 2011, p. 28). Currently, megapodes from Micronesia and Palau are considered different races of the same species, *M. l. laperouse* and *M. l. senex*, respectively (Service 1998, p. 4-5).

In general, the population status and rangewide trends of the Micronesian megapode are difficult to assess because population data have been collected and estimates have been made using a variety of methods at differing time periods. Increases and decreases in population numbers may be indicative of population trends or may reflect detection bias from implementing different survey and data analysis methods. Recent surveys and modeling suggest that islands with low human presence and without ungulates have the highest densities of the Micronesian megapode (Amidon et al. 2011).

In 2010, a survey for the Micronesian megapode was conducted in the Northern Mariana Islands. Based on the results of the 2010 surveys and previous surveys on FDM, Tinian, and Aguiguan, the rangewide population of the megapode is estimated to be a minimum of 10,827 individuals (Table 1; Amidon et al. 2011, p. 29; Service 2009b).

Table 1. Micronesian megapode population estimates based on 2010 surveys

Island	Estimated Population
Alamagan	529
Asuncion	5,714
Guguan	1,507
Maug	544
Pagan	147
Saipan	151
Sarigan	2,135
Total	10,727

Individual megapodes detected on Tinian are likely transients (Radley 2009, pers. comm.; Camp et al. 2009, p. 12; Service 2009b, p. 124; Service 1998, p. 19). FDM and Aguiguan have small megapode populations that are likely stable with the reported increase in these populations largely being attributed to improved survey methods and differences in data analysis (Service 2009b, p.124; Vogt 2009a, p. 3). However, it is also possible that the reported increase on FDM is due to dispersal of Micronesian megapodes from Anatahan due to recent volcanic eruptions (Vogt 2009, p. 4). At least 20 megapodes are estimated to occur on Anatahan (Amidon et al. 2011). The Micronesian megapode was incidentally observed once on the island of Uracus (Service 1998, p. 35). Uracus does not support forest habitat and is subject to volcanic activity on a sporadic basis, thus the likelihood of the island supporting a megapode population is low (Service 1998, p. 35).

The Micronesian megapode can use a variety of habitat types. Typically, native and secondary forest are considered the primary habitats for foraging while nesting may occur in forests, open fields, cinder and ash fields, and coastal strand edges with sand substrates. The Micronesian megapode is generally restricted on Saipan and Tinian to native limestone forest remnants along and below cliff lines and in secondary forest adjacent to limestone forest (Service 1998, p. 11). However, the association with cliff lines is likely an artifact of the location of the native forest as these uneven areas are generally the only native forest strands that were not disturbed during the long history of habitat removal on Saipan and Tinian (Service 1998, p. 11). Micronesian megapodes have been observed using tangantangan forests on Saipan (Glass and Aldan 1988, p. 142). On Aguiguan, megapodes typically occur in limestone and secondary forests, and have been observed in *Lantana* sp. scrub, but not in open areas of weedy vegetation (Service 1998, p. 11; Amidon and Kessler 2009, pers. comm.). On FDM there are stunted trees (about 7-13 feet tall) but no forest habitat (Vogt 2009a, p. 5). Micronesian megapodes were detected on FDM wherever tree or shrub cover was present (Vogt 2009, p. 5). Megapodes on islands north of FDM are present in forested habitats, including coconut forest and other native vegetation (Service 1998, pp. 11-12).

The Micronesian megapode is vocal and has been documented to duet (Service 1998, pp. 5-6 and references within). Duetting is correlated with year-round territoriality and prolonged monogamous pair bonds (Farabaugh 1982, p. 93). Duetting by the Micronesian megapode has been documented in each month of the year (Service 1998, p. 6 and references within; Amidon and Kessler 2009; pers. comm.). Glass and Aldan (1988, p. 141) reported that megapodes on Saipan remain together throughout the year in territories that are defended at least part of the year. Territory size was estimated between 2.47 acres and approximately 9.4 acres depending on the habitat type (Glass and Aldan 1988, pp. 141-142; Service 2009b, p. 124 and 126). Megapode dispersal between islands of the CNMI is not well documented. On Palau, megapodes are known to fly several miles between islands (Pratt et al. 1980, p. 121) and other species of megapodes are considered to be strong fliers (Dekker 1989, p. 317 and references within). We expect that the Micronesian megapode could fly between Saipan and Tinian (2.9 miles) or between Tinian and Aguiguan (5.5 miles) (Service 1998, pp. 9-10). The northern islands in the CNMI are 18 to 37 miles apart. Although no megapodes have been observed flying over the ocean in the Mariana Islands, anecdotal information regarding fluctuations in numbers on Tinian and the recolonization of Anatahan post-eruption suggests that they do fly between islands (Amidon et al. 2011, p. 5). Glass and Aldan (1988, p.135) reported that megapodes may have been transported by humans between islands within the CNMI, which may have assisted in maintaining its widespread distribution.

The Micronesian megapode is omnivorous and forages under ferns, branches, and leaf litter on the forest floor and in trees within bird's nest ferns (*Asplenium nidus*) (Glass and Aldan 1988, p. 142). Its diet includes seeds and other plant matter, beetles, ants, ant larvae, and other insects and crabs (Glass and Aldan 1988, p. 142; Pratt et al. 1980, p. 121; Stinson 1992, p. 230).

The reproductive cycle of the Micronesian megapode is not well understood. Megapodes, including the Micronesian megapode, do not incubate their eggs with their own body heat. Instead, megapodes will construct burrows or mounds at beaches and cinder fields, or at geothermal sites that provide heat for egg incubation. Micronesian megapodes also will make burrows or mounds in between the roots of trees and in soil with decomposing vegetation where heat generated from decomposing organic materials incubates the eggs (Decker et al. 2000, p. 2; Wiles and Conry 2001, p. 270; Glass and Aldan 1988, pp. 135-137). Micronesian megapodes lay large eggs (approximately 18 percent of the female body weight); however, the total number of eggs laid per female per breeding season, the interval between laying eggs, and the incubation period are unknown (Service 1998, p. 9 and references within). Other species of megapodes lay between 10 and 13 eggs per year (Service 1998, p. 9 and references within). In other species of megapode, eggs are laid one at a time, with each egg laid between 9 and 13 days apart (Service 1998, p. 9 and references within). Megapode chicks are precocial and able to fly upon emergence from the egg and nest (Service 1998, p. 9).

Breeding by the Micronesian megapode has been observed (eggs, chicks, and juveniles) on Anatahan, Sarigan, Guguan, Pagan, Agrihan, and Maug during all months except October, November, and December (Service 1998, pp. 6-7 and references within; Amidon and Kessler 2009; pers. comm.). The absence of breeding activity in October, November, and December is more likely a reflection of the lack of surveys during these months, and difficulty in finding megapodes during traditional avian surveys (Amidon and Kessler 2009, pers. comm.).

Factors Influencing the Current Rangewide Condition of the Micronesian Megapode

The Micronesian megapode is threatened by habitat loss and degradation due to agriculture, military operations, urban development, volcanic activity, wildfire, invasive vegetation species, overgrazing by feral ungulates (Service 1998, pp. 35-38); predation by dogs, cats, monitor lizards, pigs, and possibly rats (Dekker 1989, pp. 318-320; Dekker et al. 2000, p. 5 and references within; Service 1998, p. 37); and human exploitation (Dekker et al. 2000, p. 2; Service 1998, p. 37; Vogt 2009, p. 5; Amidon and Kessler 2009, pers. comm.). Threats from competition and disease are not well understood, but are possible. Competition for nesting and foraging areas is possible if introduced game birds and domestic or feral chickens (which forage on the same prey items as megapodes) become established in megapode habitats (Service 1998, p.38; Vogt 2009, p. 6). Additionally, the import of game birds or chickens and existing feral chicken colonies on Rota, Tinian, Saipan, Anatahan, Alamagan, and Pagan could expose megapodes to avian diseases (Service 1998, pp. 38-39), as many of these species are susceptible to West Nile virus (UC Davis 2009, pp. 2-3).

The possibility of avian flu or West Nile virus reaching the Mariana Islands from Asia or the U.S. mainland is a recent concern. The impact these two diseases may have on the Micronesian megapode is not known at this time, but both diseases have had deleterious impacts to many avian species elsewhere, and could negatively affect the Micronesian megapode if they reach the Mariana Islands. Another unknown is the potential impact of climate change on ecosystems in the Mariana Islands.

Conservation Needs of the Micronesian Megapode

The most recent 5-year status review for the Micronesian megapode (Service 2010b) lists the following conservation needs for this species:

- Survey, protect, and manage existing populations.
- Conduct essential research on the ecology and biology.
- Assess and control threats.
- Promote expansion of megapodes in suitable habitat.
- Monitor megapode populations.
- Continue implementation of BTS interdiction and control plans and establish new plans as needed.

The recovery plan for the Micronesian megapode (Service 1998) includes the following criteria for downlisting and delisting:

Downlisting Criteria

The following steps must be accomplished for downlisting: (1) a BTS interdiction and control plan must be in place and implemented throughout the Mariana Islands; (2) current threats to all extant megapode populations must be assessed and controlled; and (3) the comparatively large populations of the megapode on Anatahan, Sarigan, Guguan, Pagan, and Maug must remain at their current population levels or be increasing for 5 consecutive years.

Delisting Criteria

The total number of Micronesian megapodes in the Mariana Islands should be at least 2,650 birds distributed over 10 islands, including at least 2 populations of 600 birds or greater, 3 populations of 300 or greater, 2 populations of 200 or greater, and 3 populations of 50 or greater. All populations must be stable or increasing for 5 consecutive years after achieving these levels.

At this time, none of the recovery criteria in the recovery plan have been met. Of particular concern is the lack of an archipelago-wide BTS interdiction and control plan.

STATUS OF THE MARIANA FRUIT BAT

Species Description. The Mariana fruit bat or flying fox, known as "fanihi" in Chamorro, is a medium-sized fruit bat in the family *Pteropodidae* that weighs 0.66 to 1.15 pounds. Males are slightly larger than females. The underside (abdomen) is black to brown with gray hair interspersed that creates a grizzled appearance. The shoulders (mantle) and sides of the neck are bright golden brown, but may be paler in some individuals. The head varies from brown to dark brown. The well-formed, rounded ears and large eyes give the face a canine appearance.

Listing Status. The Guam population of the Mariana fruit bat was listed as endangered in 1984 (Service 1984). In 2005, the subspecies was listed as threatened throughout the Mariana archipelago and downlisted to threatened on Guam (Service 2005); that rule includes a complete five-factor analysis of the species' status, life history requirements, habitat needs, threats, and management efforts to conserve the Mariana fruit bat. On October 28, 2004, approximately 376 ac were designated as critical habitat for the Mariana fruit bat on Guam (Service 2004). All of the critical habitat for this species is designated on the fee simple portion of the Guam National Wildlife Refuge.

Distribution, Numbers, and Reproduction

Historic and Current Distribution. This subspecies of *Pteropus mariannus* is endemic to the Mariana archipelago, where it is present on most of the 15 islands. To the best of our knowledge, there are no records of fruit bats on Uracas, and only a few incidental observations of fruit bats have occurred on FDM (see Environmental Baseline section below). No known historical records exist to document the status of the Mariana fruit bat prior to the 20th century.

The total population of the Mariana fruit bat is estimated to be approximately 6,000 animals (USGS 2010, p. 36; CNMI 2011, p. 6). Surveys suggest populations are stable or declining throughout most of their range. Surveys on most or all of the islands in the archipelago were

conducted in 1983 (Wiles et al. 1989), 2000 (Cruz et al. 2000a-f), 2001 (Johnson 2001), and 2010 (USGS 2010, p. 1). The relatively isolated northern islands support the majority of the fruit bats in the archipelago, but because of their remote location, these islands have not been surveyed as frequently as the southern islands (i.e., Saipan, Tinian, Aguiguan, and Rota). Individual surveys have been conducted on several of the southernmost islands at relatively frequent intervals (e.g., USGS 2010, Kessler 2000; Worthington et al. 2001; Wiles and Johnson 2004). A comparison of survey results was excerpted from the USGS 2010 report (see Table 2 below). An interpretation of these data indicates a 41 percent decline in fruit bat numbers between 1983 and 2010 in the northern islands. The majority of this decline was recorded on two of the three largest northern islands, Anatahan and Pagan, which together harbored roughly 70 percent of the archipelago's fruit bats in the 1980s (Wiles et al. 1989).

A notable exception to the declining trend is the island of Rota, where the population has increased since 2008 (CNMI 2008, p. 11; CNMI 2011, p. 6). The population increase on Rota is due to a recent decrease in illegal hunting at roost sites of fruit bat maternity colonies, and the decrease in illegal hunting can be attributed to an increase in enforcement of wildlife regulations that began in 2009 (CNMI 2010, pp. 7-9).

The fruit bat population on Rota is estimated at approximately 2,600 (CNMI 2011; p. 6). Although comprehensive surveys have not been conducted on Saipan, there have been no confirmed observations of maternity colonies in recent years, and the island-wide population is expected to be less than 50 individuals (T. Willsey, pers. comm. 2014). On Guam, the sighting of fruit bats was considered to be "not...uncommon" in the 1920s (Crampton 1921). Woodside (1958) reported that in 1958, the Guam population was estimated to number no more than 3,000, although the method used to make this estimate is not known. This estimate had dropped to between 200 and 750 animals by 1995 (Wiles et al. 1995, Wiles 1996). The current population of fruit bats on Guam is estimated to be less than 30 bats (SWCA 2013, pp. 19-22; NAVFAC 2013, pp. 11-15). The most recent and last colony to exist on Guam was at Pati Point, but recent surveys indicate that this colony no longer exists (SWCA 2013, pp. 19-22). On July 3, 2014, a morning survey was conducted on Andersen Air Force Base which resulted in the observation of ten bats; however the data is being analyzed to determine duplicate observations and detection probability given the amount of area surveyed on the Base (Mildelstein 2014).

Ecology. During the day, Mariana fruit bats roost in colonies of a few to over 800 individuals (Wiles 1987; Pierson and Rainey 1992; Worthington and Taisacan 1995). Bats are typically grouped into harems (one male and two to 15 females) or bachelor groups (predominantly males). Some single males reside at the colony's periphery (Wiles 1987a). On Guam, the average estimated sex ratio in one colony varied from 37 .5 to 72. 7 males per 100 females (Wiles 1982a).

Table 2. Summary of the maximum number of bats counted in 2010 (USGS 2010, p. 36).

Summary of the maximum number of bats counted at Anatahan, Sarigan, Guguan, Alamagan, Pagan, Agrihan, Asuncion, and Maug from this study and minimum population estimates reported by Johnson (2001), Cruz and others (2000a-f), and the 1983 findings by Wiles and others (1989). Superscripts denote method(s) used to arrive at the maximum number of bats counted or minimum population estimate. Asterisks denote studies with some island estimates that were arrived from multiplying counts by a correction factor; adjusting counts based on size of island, amount of forest cover, plant diversity and abundance; or combination of these variables.

Island	2010	2001*	2000*	1983*
Anatahan	150[a]	1,000[g]	1,000[b,e,f]	3,000[c,f]
Sarigan	157[b]	400[a,b,d]	150-200[b,e,f]	125[e]
Guguan	226[c]	550[b]	350[b,c,e,f]	400[e]
Alamagan	86[d]	100[g]	200[e,f]	0[e]
Pagan	1,017[d]	1,500[a,b,c]	1,500[c,e,f]	2,500[c,f]
Agrihan	858[d]	1,000[a]	1,000[b,c,e,f]	1,000[c,e]
Asuncion	573[b]	800[a,e,f]	NA	400[e]
Maug	11[b]	50[g]	NA	<25[g]
TOTAL	**3,078**	**5,400**	**NA**	**7,450**

a. Visual estimate from helicopter.
b. Direct counts of bats at roosts.
c. Exit count of bats at roosts.
d. Counts of bats in photograph taken from helicopter.
e. Evening flight activity count (aka, station count).
f. Visual sightings from the ground.
g. Estimate not based on a count taken during that study.

Reproduction in Mariana fruit bats has been observed year-round on Guam (Perez 1972; Wiles 1983) and on Rota; individual females have a single offspring each year (Pierson and Rainey 1992). Wiles (1987) found no apparent peak in births on Guam, but a peak may occur in May and June on Rota (Glass and Taisacan 1988). Although specific data for the Mariana fruit bat are lacking, female bats of the family *Pteropodidae* have one offspring per year, generally are not sexually mature until at least 18 months of age, and have a gestation period of four to six months (Pierson and Rainey 1992). The average lifespan of this species is unknown; the longevity of a similar species in Australia is four to five years, with a maximum of eight years (Yardon and Tidemann 2000).

Roost sites are an important aspect of the Mariana fruit bat's biology because they are used not only for sleeping, but also for grooming, breeding, and intra-specific interactions (Service 1990). Published reports of roost sites on Guam indicate these sites occur in mature limestone forest and are found within 262 to 328 ft of tall cliff lines (Service 1990). On Guam, Mariana fruit bats prefer to roost in mature *Ficus* spp. and *Mammea odorata* trees, but will also roost in other tree species such as *Casuarina equisetifolia, Macaranga thompsonii, Guettardaspeciosa,* and *Neisosperma oppositifolia* (Wheeler and Aguon 1978; Wiles 1981, 1982b). On other islands in the Mariana archipelago, Mariana fruit bats have been observed in secondary forest and *Casuarina equisetifolia* groves (Glass and Taisacan 1988, Worthington and Taisacan 1996,

Worthington et al. 2001). Factors involved in roost site selection are not clear, but data from Guam indicate that some sites may be selected due to their inaccessibility by humans. Fruit bats may abandon roost sites if disturbed (Julia Boland, Service, pers. comm. 2015). Fruit bats have been reported to move to new locations up to six miles away in response to disturbance (Service 1990).

Several hours after sunset, bats depart their roost sites to forage for fruit and other native and non-native plant materials such as leaves and nectar (Service 1 990). This species feeds on a variety of plant material but is primarily frugivorous (Wiles and Fujita 1992). Specifically, Mariana fruit bats forage on the fruit of at least 28 plant species, the flowers of 15 species, and the leaves of two plant species (Wiles and Fujita 1992). Some of the plants used for foraging include *Artocarpus* sp., *Carica papaya, Cycas circinalis, Ficus* spp., *Pandanus tectorius, Cocosnucifera,* and *Terminalia catappa.* Many of these plant species are found in a variety of forested habitats on Guam, including limestone, ravine, coastal, and secondary forests (Stone 1970; Raulerson and Rhinehart 1991). Little is known about their nightly movements, but fruit bats have been observed foraging as far as 7 miles from roosting sites on Guam (Wiles et al. 1995).

Factors Influencing the Current Rangewide Condition of the Mariana Fruit Bat

The loss and degradation of native forest, illegal hunting of the species, and predation by the BTS are the primary threats to the survival of the Mariana fruit bat in the wild (Service 2005).

Conservation Needs of the Mariana Fruit Bat

A draft revised recovery plan for the Mariana fruit bat (Service 2009a) addressed actions needed for the survival and recovery needs of the Mariana fruit bat. Since publication of the draft revised recovery plan new information on the Mariana fruit bat has resulted in changes to how we look at recovery for the species. We now consider recovery in terms of stable or increasing subpopulations of sufficient size distributed across Guam and the Mariana Islands. To meet recovery objectives, stable or increasing fruit bat subpopulations should at a minimum be distributed on the islands that currently have extant populations. Actions to address the survival and recovery needs of the Mariana fruit bat are listed below (Service 2009a):

- Outreach, education, and enforcement programs need to be implemented to control illegal hunting of the Mariana fruit bat.

- Sufficient amounts of functional habitat need to be protected and restored to support persistent subpopulations of the Mariana fruit bat.

- Ungulates on Guam, Rota, Tinian, Aguiguan, and Saipan need to be controlled.

- Invasive plant species that limit native forest persistence and sustainability in areas supporting fruit bat subpopulations need to be controlled.

- Control of the BTS threat on Guam and prevention of the introduction of the BTS elsewhere within the Mariana Islands needs to be achieved.

- Control and management of other invasive species on the Mariana Islands and prevention of further inter-island transport and introduction of invasive species on the Mariana Islands needs to be achieved.

- Development and implementation of conservation projects is needed on Federal and non-Federal lands that are necessary to support persistent subpopulations of the Mariana fruit bat.

- Additional fruit bat monitoring and research is needed to better inform effective subpopulation management.

ENVIRONMENTAL BASELINE

The preamble to the implementing regulations for section 7 of the ESA provides good context for understanding the meaning of the term "Environmental Baseline." On page 19932 of the regulations (51 FR 19926), it states "In determining the "effects of the action," the Director first will evaluate the [rangewide] status of the species or critical habitat at issue. This will involve consideration of the present environment in which the species or critical habitat exists, as well as the environment that will exist when the action is completed, in terms of the totality of factors affecting the species or critical habitat. The evaluation [of the rangewide status of the species] will serve as the **baseline** [emphasis added] for determining the effects of the action on the species or critical habitat. The specific factors that form the environmental baseline are given in the definition of "effects of the action…"

Under the regulatory definition of "Effects of the action" at 50 CFR 402.02, it states: "…The environmental baseline **includes** [emphasis added] the past and present impacts of all Federal, State, or private actions and other human activities in the action area, the anticipated impacts of all proposed Federal projects in the action area that have already undergone section 7 consultation, and the impact of State or private actions which are contemporaneous with the consultation in process." Use of the term "includes" referenced above acknowledges that the environmental baseline considers the present range-wide environment in which the species or critical habitat exists as well as the specific environmental conditions in the action area. The discussion of Environmental Baseline below addresses the current condition of the listed species in the action area, the factors responsible for that condition, and the role of the action area in the survival and recovery of the species. The findings presented under the *Status of the Species* and the *Environmental Baseline* sections of this Opinion for each listed species addressed herein provide essential context for interpreting the significance of any adverse or beneficial effects of the proposed action considered herein as well as for interpreting the significance of any adverse or beneficial cumulative effects reasonably certain to occur in the action area for this consultation.

Micronesian Megapode

Current Condition of the Micronesian Megapode in the Action Area

The following information supplements the *Status of the Species* discussion above regarding the status of and threats to the Micronesian megapode on the portions of Guam, Rota, Tinian, Saipan, and the FDM that are likely to be affected by the proposed action.

The Micronesian megapode was extirpated from Guam and Rota in the ninetieth and early twentieth centuries (Service 1998, p. 3 and 15). Amidon et al. (2011) reported an anecdotal observation of a megapode on Rota in 2010. If the Micronesian megapode persists on Rota, it is likely confined to limestone forested portions of the island and not collocated with potential training areas.

The few megapode detections on Tinian are likely transient individuals that do not breed there (O'Daniel and Kreuger 1999, Navy 2013a,b). Megapodes have been sighted within forested portions of the Maga area to the northwest of the Voice of America Relay Station, a small section of native forest adjacent to Cross Island Road in the Bateha area, and the Mount Lasso area south of the overlook on the ridgeline (O'Daniel and Kreuger 1999). Based on these sightings and other suitable habitat indicators, the Navy-established monitoring transects in 1999, which were surveyed on a monthly basis through 2011 using point count stations where trained observers listened for responses to recorded megapode vocalizations. The Navy re-evaluated this methodology and determined that a larger survey conducted approximately once per year would be more likely to detect megapodes (Navy 2013b). One megapode was observed on Tinian in February of 2013 using this new methodology. Prior to this detection, one megapode was observed in February 2004 and two others in June 2005 by biologists transiting between point count stations (Navy 2013b).

The action area on Tinian includes the Exclusive Military Use Area, which consists of 7,600 acres of land in the northern one-third of Tinian (Navy 2009, p. 3.11-26). The Exclusive Military Use Area is leased by DoD from the CNMI. The action area on Tinian also includes the Military Lease Back Area, which includes the central one-third of the island and consists of 7,800 acres (Navy 2009, p. 3.11-27). Habitats on Tinian pre-World War II were extensively altered for agriculture. Military actions (both bombing during World War II, reconstruction, and ongoing training), fire, and invasive vegetation species encroachment continue to shape the habitat. Currently, both military areas support lowland habitats consisting of native forest, tangantangan thickets, secondary growth forests, and open fields (Navy 2009, pp. 3.11-26, 3.11-28). Although Micronesian megapodes were not detected on Tinian during 2008 (Service 2009b, p. 124), both action areas on Tinian support foraging and roosting habitat for the Micronesian megapode (Navy 2009, pp. 3.11-26, 3.11-44). Incidental reports and regular sightings (1995 to 2005) of the Micronesian megapode on Tinian indicates that either a small but persisting population of Micronesian megapodes exists on Tinian or that Micronesian megapodes routinely use habitats on Tinian when flying between Aguiguan and Tinian or Tinian and Saipan (Service 1998, pp. 10, 18; Navy 2009, p. 3.11-44). Due to the presence of suitable habitat and the occasional but routine observations of Micronesian megapodes on Tinian, the Micronesian megapode is at least transient and reasonably certain to occur within the Military Lease Area on Tinian.

On Saipan, Amidon et al. (2011) estimated a population between 130 and 174 Micronesian megapodes. Previous studies on Saipan provide lower island-wide population estimates, but these lower estimates are likely due to a less thorough survey effort relative to the 2010 surveys on Saipan (Amidon et al. 2011). Almost all of the detections of the megapode on Saipan occurred in native limestone forest, including detections in small remnant patches of limestone forest. Amidon et al. (2011) surveyed a transect adjacent to the Marpi Maneuver Area, and verified the continued persistence of a megapode population below the Marpi cliffs (the Marpi Maneuver Area is north of and below the Marpi cliffs). Remnant patches of limestone forest occur within the Marpi Maneuver Area, and may support Micronesian megapodes (Navy 2014a, p. 57). Figure 3-5 in the BA shows the distribution of megapode detections by Saipan-based Service staff as of 2013 adjacent to the Marpi Maneuver Area.

On Saipan, the Army Reserve Center and Commonwealth Port Authority actions areas do not support habitat for the Micronesian megapode, nor have megapodes been detected within these areas. The Marpi Maneuver Area is located on the northern portion of the island approximately one mile north and below the cliff line from the Saipan Upland Mitigation Bank (Navy 2009, p. 3.11-24). Craig (1993, pp. 99-100) summarized the habitat disturbance on Saipan and noted the Marpi area, except some of the limestone escarpments, was cleared for sugarcane (*Saccharum officinarum*) cultivation and developed for military operations during World War II. In areas where vegetation was allowed to re-grow post World War II, non-native species are the dominant vegetation. Currently, the Marpi Maneuver Area is still dominated by elephant grass (*Pennistum purpureum*) meadows and tangantangan thicket (Navy 2009, p. 3.11-24 through 3.11-25) and a remnant area of limestone forest (Navy 2009, p. 14) and this area is used to support recreation and tourism, agricultural leases, and homesteads.

Between the cliff line and the Marpi Maneuver Area is a 43-acre protected area for the Micronesian megapode (USEPA 2009, pp. 2, 8). The protected area is known to support at least one Micronesian megapode (Rounds 2009, pers. comm.). Other areas, including tangantangan thickets adjacent to limestone forests and elephant grass meadows adjacent to the Marpi Maneuver Area, are known to support Micronesian megapodes as well (Mosher 2009; Service 2002, p. 8).

The Micronesian megapode may be using scattered tangantangan strands within the Marpi Maneuver Area for feeding, resting, and as a corridor between limestone forests. Because of the continued sightings of the Micronesian megapode in adjacent limestone forest, the Micronesian megapode is reasonably certain to occur within the Marpi Maneuver Area on Saipan (Shelly Kremer, Service, pers. comm. 2015).

FDM is leased by the DoD from the CNMI and is approximately 183 acres in size (Navy 2009, p. 3.11-29). Habitat used by the Micronesian megapode on FDM is characterized as predominantly dense herbaceous communities, scrubby brush, stunted trees, grasslands, and bare earth and include the following plant species: *Wollastonua biflora*, *Mariscus javanicus*, *Capparis spinosa*, *Ipomoea pes-caprae*, *Boerhavia* spp., *Portulaca lutea*, *Operculina ventricosa*, and stunted *Pisonia grandis* (Lusk et al. 2000, p. 24; Navy 2009, p. 3.11-30). The habitat is maintained in a low to mid-successional stage due to wind conditions (northern portion) and previous military readiness training (middle and southern portion) (Navy 2009, p. 3.11-61).

Surveys on FDM in 1996 documented the presence of the Micronesian megapode (Lusk et al. 2000; Service 1998). Based on this survey, a population of 10 Micronesian megapodes was estimated to occur on FDM (Lusk et al. 2000; Service 1998). However, due to an approaching typhoon, biologists conducting the survey were only on the island for about 5.5 hours, so this estimate was based on limited data. FDM was surveyed more thoroughly in December 2007 by Navy biologists, who estimated 21 adult megapode pairs on the island (Navy 2008a,b). Vogt (2009, pp. 3, 5) reported the observation of a chick and a juvenile Micronesian megapode indicating that reproduction is occurring on the island. Based on the size of FDM and the potential territory size of the Micronesian megapode, Vogt (2009, p. 4) estimated that the island could likely support a population of 50 megapodes. The most recent megapode survey on FDM was completed in 2013. Navy biologists detected 11 megapodes while surveying a limited transect in the north part of the island (within impact areas 1 and 2) (Navy 2013d). Measures implemented by the Navy under the MIRC program likely minimized impacts to the megapode population on FDM. These measures included maintaining a No Drop Zone on the northern portion of the island and the use of inert ordnance in an area south of the No Drop Zone (explosive ordnance is deployed south of this area). Megapodes have persisted on FDM through various phases of intense bombardment of the island from the 1970s to the present.

Factors Influencing the Condition of the Micronesian Megapode in the Action Area

On Saipan and Tinian, ongoing implementation of the MIRC program is causing noise from aircraft and vehicles, physical disturbance caused by vehicles and people, and the potential for introduction of invasive species are factors that are or may influence the current condition of the Micronesian megapode within the Action Area (see Table 3-2 in the BA).

On FDM, ongoing implementation of the MIRC program is causing noise from aircraft, percussive force caused by explosives, direct strikes by aircraft and munitions, physical disturbance caused by vehicles and people, habitat loss and degradation, the potential for introduction of invasive species, and wildland fire are factors that are or may influence the current condition of the Micronesian megapode (see Table 4-2 in the BA). The avoidance and minimization measures currently being implemented on FDM by the DoN are designed to protect the area of the island occupied by the Micronesian megapode in the "No Drop Zone." As of 2000, Lusk et al. (2000, p. 33) reported that the vegetation and avian communities in that area had not changed substantially since 1974. While these data were not specific to the megapode, this may be an indication that the avoidance and minimization measures are providing some level of protection to the species and its habitats in this area while military training occurs on FDM. However, take of the Micronesian megapode is likely occurring on FDM due to military training activities (Service 2010a).

Role of the Action Area in the Conservation of the Micronesian Megapode

The final recovery plan for the Micronesian megapode identifies the need to maintain a stable or increasing population of 50 megapodes on Saipan or Tinian (Service 1998, p. 43).

Although FDM is not essential for recovery (Service 1998, pp. 42-42), the DoN's implementation of the avoidance and minimization measures discussed above has resulted in the persistence of a small population of Micronesian megapodes in the "No Drop Zone." That

population may provide a genetic link between the northern and southern populations of the rangewide population of the megapode, and FDM may function as a rest stop for dispersing megapodes (Lusk et al. 2000, p. 29).

Mariana Fruit Bat

The following information supplements the *Status of the Species* discussion above regarding the status of and threats to the Mariana fruit bat on the portions of Guam, Rota, Tinian, Saipan, and the FDM that are likely to be affected by the proposed action.

Current Condition of the Mariana Fruit Bat in the Action Area

The following discussion relies heavily on the findings presented in the BA for the proposed MITT program (Navy 2014a) and on the Service's draft revised recovery plan for the Mariana fruit bat (Service 2009a).

Guam

On Guam, the sightings of Mariana fruit bats were considered to be "not...uncommon" in 1920 (Crampton 1921 in Service 2009a). In 1958, the Guam population was estimated to number no more than 3,000. This estimate had dropped to between 200 and 750 animals by 1995. Over the past several decades, the population of fruit bats on Guam has continued to decline (Brooke 2008). Other than a few isolated periods of increase, fruit bats have been in long-term decline on Guam (Service 2009a). The population of fruit bats on Guam is estimated to be less than 30 bats (SWCA 2013, pp. 19-22; NAVFAC 2013, pp. 11-15). The primary threats include poaching, predation (primarily by the BTS on fruit bat pups), and low population size reducing gene flow (Service 2009a). Recently completed and ongoing ESA section 7 consultations between the DoD and the Service include habitat removal actions associated with remedial cleanup activities as part of the Andersen AFB Installation Restoration Program (Consultation # 2013-I-0392, Service 2013), ISR Strike (Consultation # 2006-F-0266, Service 2006a), Parachute Cargo Drop Training at Northwest Field (Consultation # 2001-F-0001, Service 2001), Beddown of Training and Support Initiatives at Northwest Field Project (Consultation # 2006-I-281, Service 2006b) and the missile defense system at Northwest Field (emergency consultation pending). These projects may increase the vulnerability of the Mariana fruit bat to adverse effects caused by the training activities included in the BA for the MITT program.

On Andersen AFB, individual bats and small groups have been observed roosting in both primary (mature and native-dominated) and secondary growth limestone forest cover (Janeke 2006). The majority of the bats at Andersen AFB roosted at a single site on Pati Point, and an unknown number of solitary bats use the limestone and secondary forests of Guam. Fruit bats forage in forests and coastal areas, and they are occasionally sighted at Tarague Beach (USAF 2008a, b, c, d).

The Mariana fruit bat colony on Andersen AFB has used the same roost location at Pati Point since 1994. Except for the punctuated increase in the early 1980s, the overall population trend of this species at this site has been declining. In 2006, Janeke (2006) estimated fewer than 100 fruit bats at Pati Point. A survey conducted on Andersen AFB from June 2007 until April 2008 indicated counts from 31 to 54 individuals with an average count of 40 bats (SWCA

Environmental Consultants 2008). Surveys in 2011 by SWCA observed 2 to 3 bats below Pati Point, but the colony is no longer present and surveys have not found that the colony has relocated (SWCA Environmental Consultants 2012). Northwest Field likely continues to support Mariana fruit bat foraging, and possibly solitary roosts in the intact limestone forests above the plateau at Ritidian Point and along the northeast fringe of Northwest Field.

The Mariana fruit bat is rarely observed at Naval Base Guam. The last recorded fruit bat occurrence on the Orote Peninsula was of a colony of 332 in 1967. A single bat was sighted on Naval Base Guam lands in 2008 during 90 hours of fruit bat surveys at 14 survey locations there and on nearby lands. A small number of solitary bats may persist on Naval Base Guam, however, it is possible that solitary individuals move to and from areas throughout the year.

Mariana fruit bats were seen sporadically on the Naval Base Guam Munitions Site between 1985 and 1999 (Morton and Wiles 2002). In 2010, three sightings of the same individual Mariana fruit bat were reported within the Naval Base Guam Munitions Site. Seven observations of one Mariana fruit bat in flight, each on a different day, were recorded at the Naval Base Guam Munitions Site between 10 May and 22 June, 2012 (Navy 2014a, p. 38). On August 27, 2014, two observations of a Mariana fruit bat in flight occurred at the Fena Reservoir within the Munitions Site (Leilani Takano, Service, pers. comm. 2014). It could not be determined if these observations at the Munitions Site represented one or multiple individual fruit bats.

Mariana fruit bats may forage or roost in the Finegayan area of Naval Base Guam, Telecommunication Site (Navy 2013a). Naval Base Guam Barrigada does not likely support fruit bat roosting sites, however, foraging activity possibly occurs there.

Mariana fruit bat surveys were conducted at Andersen South between 18–20 March 2013 (Vogt and Farley 2013). No bats were detected during these surveys. There are no recent records of Mariana fruit bat use of the Andersen South area.

Rota

The fruit bat population on Rota is estimated at approximately 2,600 (CNMI 2011; p. 6) and has increased since 2008 (CNMI 2008, p. 11; CNMI 2011, p. 6) due to a recent decrease in illegal hunting at roost sites of fruit bat maternity colonies. The decrease in illegal hunting can be attributed to an increase in enforcement of wildlife regulations that began in 2009 (CNMI 2010, pp. 7-9). Mariana fruit bats from Rota move episodically among the southern islands, and this island thus is considered to be important to the long-term stability of the species in the southern part of the Mariana archipelago and to the sporadic existence of the colony on Guam (Wiles and Glass 1990; Wiles et al. 1995).

Illegal hunting is the primary threat to Mariana fruit bats on Rota. Although law enforcement efforts have increased since 2009 (CNMI 2008, 2009a-b, 2010), illegal hunting continues and will likely resume to historical levels unless consistent, effective law enforcement in tandem with education and outreach programs continue. Recovery of the fruit bat on Rota and other human-inhabited islands will not likely be possible without strong education programs combined with effective control of illegal hunting. It is unlikely that the naturally low reproductive rate of this species can sustain the level of hunting pressure currently observed on Rota.

Severe storms (and associated hunting) at short intervals combined with low and fluctuating numbers could erode what resilience exists in this population. Fruit bat numbers on Rota declined following Typhoon Roy in 1988 from an estimated 2,400 animals to just under 1,000 (Stinson et al. 1992). Prior to Typhoon Pongsona in 2002, fruit bat numbers on Rota had risen to about 1,300-2,000 bats (Esselstyn et al. 2006). However, in the months following the storm, repeated surveys indicated that numbers had again declined sharply to perhaps 500 bats (Esselstyn et al. 2006). The number of fruit bats detected by surveys remained relatively low through April 2004, when about 700 bats were counted (Esselstyn et al. 2006

Saipan

Schnee (1911; cited in Service 2009a) reported that Mariana fruit bats were commonly seen and heard on Saipan, where they were heavily hunted by local residents. The Navy restricted civilian access to the northern part of Saipan until the early 1970s, effectively providing the bats with protected roost sites. Fruit bats on Saipan were observed to decline rapidly after the Navy turned over control of this area to the CNMI government, and access to the entire island became unrestricted (Wiles et al. 1989). Observations made between the late 1970s and 2007 suggest that Saipan harbored a small number of bats during that period; typically 50 bats or fewer (Wheeler 1980; Lemke 1984, cited in Service 2009a; Glass and Taisacan 1988; Wiles et al. 1989; Worthington and Taisacan 1996; Johnson 2001; Ann Marshall, Service, pers. comm. 2007).

Tinian

Fritz (1901; cited in Service 2009a) reported a "large number" of bats on Tinian in 1900. Since the late 1970s fruit bats have been seen rarely and only in small numbers, with estimates of fewer than 25 animals usually given for the island (Wheeler 1980; Glass and Taisacan 1988; Wiles et al. 1990; Marshall et al. 1995; Krueger and O'Daniel 1999; Johnson 2001). Observations during the 1990s suggested that the presence of bats on Tinian was intermittent, and their numbers were low (Worthington and Taisacan 1996). Brief surveys on Tinian conducted in 2001 found no fruit bats (Johnson 2001), and between 2002 and 2007 fruit bats have been observed only once during forest surveys conducted on Tinian each month by Navy biologists (Scott Vogt, Navy, pers. comm. 2007). A few Mariana fruit bats were observed on Tinian during surveys conducted by the Navy, and island residents reported occasionally seeing Mariana fruit bats (Navy 2008a). Mariana fruit bats also reside on Aguiguan and travel to Tinian to forage (Cruz et al. 1999, 2000, 2002). In June 2005, approximately five Mariana fruit bats were seen in the cliff-line forest during a routine forest bird survey of the Maga bird transect (Navy 2008a).

FDM

FDM may serve as a stopover location for Mariana fruit bats while transiting between islands or may support a small resident population. Incidental observations of Mariana fruit bats on FDM during recent bird surveys, along with fisherman reports from the early 1970s, suggest a small number of Mariana fruit bats use FDM. Use of the island by Mariana fruit bats may have been greater prior to the use of the island as a bombing range. A historical photograph included in the BA (p. 77) shows a more intact, forested areas on the mesic flats in the northern portion of the island than is the case today based on the photograph of the same area taken in 2013 (see BA, p. 77). This forested area likely provided foraging and roosting habitats for the Mariana fruit bat.

Factors Influencing the Condition of the Mariana Fruit Bat in the Action Area

As discussed above under the *Status of the Species*, poaching, habitat loss and degradation caused by humans (inclusive of human disturbance at roosting sites and military bombardment on FDM) and feral ungulates, and invasive plants are the primary factors influencing the condition of the Mariana fruit bat in the Action Area.

Role of the Action Area in the Conservation of the Mariana Fruit Bat

The draft revised recovery plan for the Mariana fruit bat (Service 2009a), considers federally administered lands in the Mariana Islands to be important sites for the protection and management of the Mariana fruit bat and its habitat. The maintenance and enhancement of fruit bat populations, especially through habitat preservation, restoration, and creation, on these lands, inclusive of those associated with the MITT program, is fundamental to the conservation and recovery of this species.

EFFECTS OF THE ACTION

Invasive Species Transport and Introduction

As discussed in the BA (see pp. 66 and 83), the Navy recognizes the potential for catastrophic effects to wildlife on Rota, Tinian, Saipan, and the FDM resulting from the accidental introduction of the BTS or other vertebrate predators from Guam or elsewhere. Accidental introductions of potentially invasive pests and plants could establish populations and further degrade habitats on these islands. Rota is of particular concern because of close proximity and shorter transit times from Guam and because of the high quality habitats located throughout the island. Figure 2-6 in the BA (p. 38) shows a conceptual model of potential pathways of invasive species introductions to Rota, Tinian, Saipan, and the FDM. These islands are linked together and to Guam by marine and air transportation routes that support military training activities. The Navy's strategy to avoid and minimize the adverse effects of invasive species introductions is to identify critical control points within the potential pathways depicted in Figure 2-6 of the BA, then design and implement exercise-specific invasive species interdiction plans. Such an approach is currently being implemented under the MIRC program.

Under the proposed MITT program, the Navy proposes to implement the following measures; these are described in more detail in Appendix B:

- Upon completion of the MIRC Reinitiation BO and other pending consultations, Navy will update the COMNAVMARIANASINST 3500.4A to reflect the language contained in these Biological Opinions applicable to range users. Navy will also finalize a new Joint Region COMNAVMAR Brown Treesnake instruction, which will contain the Brown Treesnake Control and Interdiction Requirements. These efforts shall be prepared in coordination with the Service and other stakeholder agencies.

- Training activities will undergo a pathway risk analysis as a tool to improve programmatic efficiency while preventing the spread or introduction of BTS.

- The Navy, in compliance with Public Law 110-417, [Division A], title III, Section 316, October 14, 2008, 122 Statute 4410 and per Department of Defense (DoD) Transportation Regulations, Chapter 505 protocols, is committed to implementing 100% inspection of all aircraft and all cargo/equipment leaving Guam via vessel or aircraft for an off-island destination with trained brown treesnake personnel and qualified canine detection teams. The skills and standards required to certify personnel, including canine inspection teams, as "qualified" will be agreed upon mutually by DoD and the Service. These teams may be supplemented with qualified personnel to meet 100 percent inspection goals for training activities.

- In the event military units, vehicles, or equipment accidentally leave Guam without inspection, as soon as possible, the Navy will notify the qualified brown treesnake interdiction program and the destination port or airport authorities. The Navy will work with the destination authority(ies) to resolve the issue. Urgency of notification is a priority so that rapid response or other actions can be implemented to reduce risk, if warranted.

- To the maximum extent practicable, the Navy will route inbound personnel and cargo for tactical approach exercises (that require an uninterrupted flow of events) directly to CNMI training locations to avoid Guam seaports and airfields to the extent possible. If Guam cannot be avoided for tactical approaches, the Navy will work with the U.S. Fish and Wildlife Service to identify and implement appropriate interdiction methods at the receiving port (Rota, Saipan or Tinian). Methods may include redundant inspections or other interdiction actions, such as multiple inspections or barrier use on Guam. In addition, tactical approach exercises will involve only cargo/equipment that has not originated from areas containing a brown treesnake population or will be 100 percent inspected by qualified brown treesnake canine detection programs.

- The Navy will establish snake-free quarantine areas (barriers) as deemed necessary by the Navy and U.S. Fish and Wildlife Service for cargo/equipment traveling from Guam to CNMI and locations outside of the MITT action area. Barriers will be used if the volume of cargo/equipment/vehicle movement out-paces the available canine inspection capacity or BTS quarantine capacity. The snake-free quarantine areas will be subject to: (1) multiple day and night searches with appropriately trained interdiction canine teams, (2) snake trapping, and (3) visual inspection for snakes. Standard operating procedures will be developed based on the barrier size needed for the training event(s). Temporary barriers will be constructed and maintained in a manner that assures the efficacy of the barrier. Staff constructing and maintaining the temporary barriers will receive training related to this activity prior to barrier construction and operation. Barrier specifications as well as the qualifications of BTS barrier maintenance and management staff will be mutually agreed upon by DoD and the Service.

- Navy will (1) coordinate closely with the Service[1] and the CNMI Department of Land and Natural Resources staff on planning for training activities in the CNMI; (2) coordinate with the other DoD action agencies implementing the MITT program and the Service to identify

---

1 Currently, the Service point-of-contact (POC) for these planning activities is the CNMI Brown Tree Snake Program Coordinator (Coordinator). If the agency affiliation of that Coordinator changes, the Service shall formally designate a new Service POC and advise the DON and other DOD action agencies associated with the MITT Program within 10 working days.

the inspection and interdiction requirements for MITT program-related training activities, including the number of trained quarantine officers and canine detection teams required to ensure that the inspection and interdiction requirements for MITT program-related training activities can be met; (3) coordinate with the Service on the inspection and interdiction requirements identified by the Navy prior to the implementation of the exercise or training activity; and (4) identify the support that the Navy will need to provide for the inspections and develop plans to ensure that inspection personnel are available and all requirements are met.

- Navy will utilize ongoing adaptive management to improve methods for BTS rapid response, including detection of low-density snake populations using all technologies as they become available. The Navy will annually review BTS rapid response needs with the Service to mutually determine if refined methods need to be implemented; the Navy will support such refinement based on that mutual agreement.

- MITT action proponents will provide support for BTS rapid response associated with a BTS sighting within the JRM AOR related to a MIRC program-related training activity subject to this consultation.

- Prior to each exercise that involves the movement of equipment and troops between islands, a pathway risk analysis will be conducted and biosecurity protocols confirmed by the DoD (JRM). Implementation of biosecurity protocols will be a requirement for training. An adaptive management review of risk analyses and biosecurity protocols will be conducted periodically with the Service. Initially, this adaptive management review will include the development of Standard Operating Protocols (SOPs) for biosecurity by the DoN in support of training activities covered under the MITT program. These DoN biosecurity SOPs will be reviewed by the Service when initially developed. Once the MITT program is implemented, MITT program-related SOPs will be reviewed with the Service annually.

- In coordination with the Service, the DoD action agencies implementing MITT activities will establish a contractual agreement for adequate rapid response capabilities with appropriate agencies having invasive species rapid response expertise and technology within three months of the Service's issuance of this Biological Opinion. The contracted services will focus on control and eradication of introduced non-established, non-native invasive species sighted in the vicinity of: (1) DoD MITT training areas, and (2) DoD areas and facilities used for the staging, storage and movement of MITT personnel, cargo, and MITT-associated vehicles (e.g., planes, trucks, and vessels). Priority should be given to non-native invasive species that pose a high risk of being transported elsewhere due to MITT-related training actions. This arrangement will be in place until superseded by a regional rapid response plan[2]. Monitoring will consist of the established protocols for USDA inspections, personnel awareness during pre-event preparations, and self-inspections. As noted above, an adaptive management review of risk analyses and biosecurity protocols will be conducted periodically with the Service.

---

2 The regional rapid response plan discussed refers to the full implementation of a comprehensive Emergency Response Plan for Guam and the CNMI in association with the Regional Biosecurity Plan (RBP) for Micronesia and Hawaii. The RBP is discussed further in the MIRC re-initiation / MITT Biological Opinion.

Currently, the proposed MITT program includes provisions for detecting the inter-island transport of invasive species in terms of applying established protocols for USDA inspections, military personnel awareness during pre-event preparations, and self-inspections by military personnel involved with the proposed training activities. To date, annual reports prepared by the Navy under the MIRC program that are on file at the Service's PIFWO have not reported any incidents of introduced species being transported inter-island and introduced elsewhere. However, given the proposed increase under the MITT program in the frequency of military training currently being implemented under the MIRC program (see Appendix A), it is reasonable to anticipate a higher potential for such introductions to occur under the MITT program.

Given that higher potential, the Service believes additional monitoring/response capability may be needed under the MITT program to ensure early detection and eradication of inter-island introductions of invasive species that may be caused by MITT program-related activities. During this consultation, the Service and the Navy discussed this matter and informally agreed that such capability should be provided under a multi-agency programmatic action to implement the Regional Biosecurity Plan for Micronesia and Hawaii (RBP; Navy 2015). The Navy is committed to coordinating with the Service and other stakeholders on the development and implementation of this programmatic action (D. Schregardus, Deputy Assistant Secretary of the Navy, Environment, pers. comm. to Theresa Rabot, Service, Assistant Regional Director, Ecological Services, Region 1). The Navy also requested that the Service include a conservation recommendation in this Opinion addressing this matter (see *Conservation Recommendation* section below). For purposes of this analysis, within the term of the proposed action, the Service anticipates the above programmatic action will be developed and implemented region-wide, will include an effective rapid response plan that relies on an adequate monitoring program, and will serve to supplement or replace the currently proposed biosecurity measures under the MITT program.

Micronesian Megapode

Tinian

The nature of the proposed training activities on Tinian involves noise generation by aircraft and vehicles, and the potential for transport and introduction of invasive species. No training is proposed within areas of suitable habitat for the megapode. Given that physical separation, above ambient noise levels that may disrupt the feeding or sheltering behavior of transient megapodes are considered unlikely to occur.

Saipan

On Saipan, megapodes may use the intact limestone forests located within the Marpi Maneuver Area. At least one Micronesian megapode has been detected in the limestone cliff forest across the road from and within the Marpi Maneuver Area. Under the proposed action, only pedestrian land navigation training would occur in the Marpi Maneuver Area and no training will occur in the native limestone forest. Pedestrian land navigation training is designed to facilitate navigation to a location undetected, as quietly as possible. The proposed training within the Saipan Marpi Maneuver Area would be infrequent and would avoid the limestone forest habitat used by the megapode. Further, the types of training activities that do occur within the Marpi

Maneuver Area are more likely to occur in the open, more disturbed areas away from where megapodes would likely occur. Therefore, there is little likelihood of disturbance from noise and human presence caused by the proposed military training activities.

FDM

With implementation of the proposed action, the Micronesian megapode would be exposed to noise and pressure waves from explosions on FDM from strike warfare and firing exercises. Response of the Micronesian megapode to explosive noise has not been evaluated (Service 2010a); however, Micronesian megapodes are vocal and presumably find mates and defend territories by duetting (Service 1998). Therefore, explosive noise and pressure waves generated from explosions are likely to impact the Micronesian megapode if it physically damages the ears such that the affected individual: cannot hear and locate a mate; produces abnormal calls (hearing impaired learning) and cannot attract a mate; or is unable to defend a territory.

Other concerns from noise impacts to avian species are related to nesting and impacts to eggs or chicks (e.g., mortality through kicking eggs or young out of the nest during flushing; exposing eggs or young to temperature changes during nest flushing; causing adults to not feed and care for young during nest flushing; and exposing eggs and young during nest flushing to increased predation). Micronesian megapodes generally bury their eggs in mounds in which temperature is controlled by sources other than the bird (Service 2010a). Megapode chicks are precocial, are able to fly upon emergence from the egg and do not require parental care (Service 1998). Therefore, the above behavioral responses to noise impacts typical of other avian species are not likely to be exhibited by Micronesian megapodes.

FDM supports at least 11 Micronesian megapodes, therefore, concentrations of these birds at different times of the year are likely to coincide with strike warfare training exercises. On the FDM range area where ordnance is restricted to inert munitions, vegetation is recovering in vertical structure and surface cover in contrast to range areas where high explosive ordnance is permitted (Navy 2013b). Micronesian megapodes have been observed within the inert target area, although in lower densities relative to areas north of the "special use area" where no live-fire training occurs (Navy 2013b). The potential for injury to Micronesian megapodes on FDM associated with direct strike from inert munitions is considerably lower than the potential for blast effects associated with explosive munitions. Blast effects from explosive munitions are likely to injure and kill Micronesian megapode. The Service's 2010 Opinion on the MIRC program, as amended in 2013, anticipated and authorized the incidental take by kill and injury of 5 pairs (10 individuals) of the Micronesian megapode on FDM over the 5-year term of the MIRC program in part due to the effects of strike warfare training exercises. This amount of anticipated take was derived on the basis of five pairs (ten individuals) of the Micronesian megapode being detected using the area around the inert and live-fire target areas on FDM. That level of impact on the megapode is highly likely to continue and increase under the proposed MITT program, which increases the number of bombing exercises on FDM from 1,300 per year under the MIRC program to 2,300 per year, and the number of gunnery exercises on FDM from 22 per year under the MIRC program to 96 per year (see Appendix A). On the basis of these increases in bombing, gunnery, and missile exercises, two pairs of the megapode are likely to be killed each year on FDM.

Helicopter landings and approaches, expected to occur north of the no fire line within the special use area, may expose Micronesian megapodes to aircraft strike hazards during approaches and takeoffs. More megapodes are expected to occur within this area because of higher quality habitat relative to the impact areas on FDM. The proposed action includes 18 direct action-type training activities on FDM, which is a 5-fold increase over current training operations. Micronesian megapode behavioral responses to an approaching helicopter may include flushing and flying away from the sound source, or if in air, flying away from the sound source. As a ground-nesting bird, seeking cover on the ground is also likely a reasonable response. These behavioral responses may reduce the likelihood of megapodes being struck by aircraft. Helicopter landings need to occur in open areas free of debris or woody vegetation. Although Micronesian megapodes may nest within landing areas, especially after periods of nonuse, the potential for helicopters to physically land on a nest is extremely low because of higher quality habitat in other portions of the special use area that is likely to be used for nesting by the megapode.

On FDM, Micronesian megapodes use habitats within the target areas (estimated five pairs) and within areas north of the no-fire line (estimated 16 pairs) (Navy 2009, Service 2010a). Chicks and juveniles have been observed on FDM, along with habitat manipulations suggestive of megapode burrows north of the no-fire-line (Lusk et al. 2000). Habitats within the inert and live-fire target areas south of the no-fire-line will continue to be degraded, fragmented, and possibly lost due to continued military use of the island. Strike warfare training may make habitats within the inert and live-fire areas more prone to the compounding effects of drought and typhoons, and increase fine fuel (grasses and other herbaceous vegetation) availability for wildland fires to spread into edge habitats.

Wildfire intensity may vary based on the amount and type of munitions, wind speed, levels of humidity, seasonal variation in vegetation thickness and composition, and successional state of vegetation. Fire effects in habitats used by Micronesian megapodes could include a variety of direct and indirect effects. Megapodes could be exposed to smoke inhalation, resulting in mortality, nest abandonment, or injury. Direct exposure to flames would destroy nests and may kill individual megapodes. Micronesian megapodes on FDM would be expected to fly away from smoke, but exposure to smoke inhalation would result in some form of respiratory distress (Service 2010a). Direct mortality of megapodes could result from intensive respiratory distress. Megapode eggs, even in burrows, would not likely survive a wildfire overburn. Likewise, any fledglings within a burn area would be expected to suffer intensive respiratory distress, and unable to flee smoke or burning vegetation. The likelihood of a wildland fire spreading north out of the impact zones into more intact forests on the northern portion of the island cannot be negated, however, factors such as a relatively higher fuel moisture content and mesic conditions in the higher stature vegetation may limit the spread of fires. Therefore, the northern portion of the island is likely to continue to serve as a refugium for Micronesian megapodes that either reside in this area or for megapodes able to move away from smoke and flames in the target areas. Indirect effects include a general reduction of organic matter available on FDM, such as litter and duff used by the megapode to build nests and incubate eggs.

There are three designated bombing target areas on FDM south of the no-fire zone: Impact Area 1, the northernmost of the three, is designated for inert ordnance only; Impact Areas 2 and 3 are designated for both live and inert ordnance (see Figure 4-2 in the BA). Placement of the inert-only target area farthest north provides a buffer between the live ordnance targets to the south

and the area north of the no-fire zone, providing megapodes and their more favorable habitat a degree of protection. While unintentional and not part of the proposed action, inert and live bombs may miss their intended targets and land anywhere on the island including within areas occupied by megapodes. These unintentional impacts are likely to continue and increase, with the increased bombing of FDM,

Megapodes have persisted on FDM through various phases of intense bombardment of the island from the 1970s to the present. Recent surveys in 2013 detected 11 megapodes within the limited survey area in Impact Areas 1 and 2 (Navy 2013b). Megapode densities in portions of the FDM no-fire zone are analogous to densities on other uninhabited islands considered to be refugia for this species, such as Sarigan and Guguan (Navy 2008d), suggesting that Navy measures implemented under previous actions have minimized impacts to megapodes on FDM. Although megapode numbers have increased, the frequency of explosive ordnance use on FDM will also increase under the proposed action. Coupled with the recovery of vegetation within the no-fire zone and inert ordnance zone, megapode exposure to direct mortality from munitions and potential wildfires (from increased fuel loading) will continue for the term of the proposed action (see Description of the Proposed Action above). Although a population of megapodes on FDM continues to persist on the island, military activities are likely to negatively impact all megapodes on FDM that occur inside and outside of the impact areas.

As noted above, the Service's 2010 Opinion on the MIRC program, as amended in 2013, anticipated and authorized the incidental take by kill and injury of 5 pairs (10 individuals) of the Micronesian megapode on FDM over the 5-year term of the MIRC program. Those levels of take are highly likely to continue and increase under the proposed action for the reasonably foreseeable future. Given the term of the proposed action and the proposed increases in strike warfare training on FDM as discussed above and in Appendix A, it is possible, but not reasonably certain, that the Micronesian megapode may be extirpated from FDM as a result of the MITT program. Since FDM is not considered to be essential to the recovery of the megapode (Service 1998, p. 42), that potential outcome of the proposed action is not considered to be a significant impact to the Micronesian megapode at the rangewide scale.

Mariana Fruit Bat

Guam

In addition to specific provisions for BTS interdiction and control and other biosecurity measures described above and detailed in Appendix B, the proposed MITT program also includes the following provisions (excerpted from pp. 22 and 23 of the BA; detailed in Appendix B) to avoid and minimize adverse effects to the Mariana fruit bat from training activities on Guam:

Conservation measures on Guam that limit the impacts associated with aircraft training activities include:

- Helicopter overflights as part of training activities are prohibited below 1,000 feet (305 meters) above ground level (AGL) over Northwest Field north of the South Runway. This measure is designed to minimize visual disturbance and acoustic noise impacts on foraging or roosting Mariana fruit bats in the Northwest Field area. The satellite tracking station

located at Northwest Field also has a flight restriction of 2,500 feet (760 meters) AGL within 1 nautical mile of the station.

- Overflights as part of training activities along all Andersen AFB clifflines are prohibited below 1,000 feet (305 meters) AGL.

- Helicopter overflights as part of training activities are restricted throughout the Naval Base Guam Munitions Site below 500 feet (150 meters) AGL. Fixed-wing aircraft are restricted below 1,000 feet (305 meters) AGL as part of training activities.

Conservation measures on Guam that limit the impacts associated with ground maneuvers include:

- "No Wildlife Disturbance" and "No Training Areas" are designated on Naval Base Guam Orote Point, Naval Base Guam Navy Munitions Site, and Andersen AFB Tarague Beach. Vegetation removal would be limited to maintaining existing bivouac areas. No new bivouac areas are proposed in this BA. Maneuver units will remain tactical and not establish support camps.

- All training activities that involve ground maneuvers on Guam will be consistent with the fire management plan included in COMNAVMARIANASINST 3500.4A. A description of this plan is included in BA Section 2.3.6 (Wildland Fires).

- Riparian wetlands are dispersed throughout the Southern Land Navigation. No maneuver and navigation training will occur in riparian wetlands in this area.

- The Navy will locate ground-disturbing training activities on previously disturbed sites whenever possible. Training areas, including transit routes necessary to reach training areas will be clearly marked. Vehicular activities will be restricted to designated and previously identified areas. Off-road vehicle use will only occur in designated off-road areas or on established trails.

Conservation measures on Guam that limit impacts associated with established range use include:

- The USAF implements training and operation restrictions at the Combat Arms Training and Marksmanship (CATM) range at Tarague Beach, Guam to minimize effects to sea turtles and Mariana fruit bat. Night-training occurs at the CATM range; therefore night-lighting is installed. The lighting configuration at this location is maintained with four flood lights, located below the tree canopy level that are directed inland and parallel to the coast. Lighting in this configuration will avoid impacts to nesting and hatching sea turtles and Mariana fruit bats.

- The CATM range allows for training with small arms, inert mortars to 60 millimeter, and 40 millimeter grenade launchers. These weapons do not produce percussive force and no weapons that produce percussive force can be used at this facility.

Given the above measures and considering both the current distribution and abundance of the fruit bat on Guam and the exclusion of USAF aircraft staging and takeoff and landings at Andersen AFB from the MITT program, the Service finds that implementation of the proposed MITT program on Guam:

1. Is not likely to adversely affect the roosting behavior of the fruit bat in the Action Area on Guam. Historically, the primary roosting area for the Mariana fruit bat on Guam was located at Pati Point. That roost site is not currently being used by fruit bats. Should fruit bat occupation of that site resume during the term of the proposed action, the proposed MITT program is compatible with that use.

2. Is likely to adversely affect the foraging behavior of the fruit bat as a result of noise caused by nighttime training activities particularly at Andersen AFB and the Naval Base Guam Munitions Site. However, these adverse effects are not anticipated to significantly disrupt fruit bat foraging behavior to an extent that is reasonably certain to cause injury or death of the affected bat(s) because the affected bats are likely to shift their foraging sites away from areas used for nighttime training activities.

Rota

The Service's Opinion on the MIRC program (Service 2010a) did not anticipate adverse effects to the Mariana fruit bat to be caused by proposed military training activities other than on Guam. The BA for the MITT program includes the following discussion on pages 60, 65, 66, 68, and 69 regarding the effects of the MITT program on the fruit bat on Rota:

On Rota, Mariana fruit bats are found in mature limestone forests and coconut groves on the island. Most roosting activity and colony sites occur in the Sabana region of the island (see Figure 3-1), which coincides with the Mariana fruit bat critical habitat designation. Military training activities do not occur in these areas, however, Mariana fruit bats may be exposed to noise from training activities based out of the Rota International Airport. Mariana fruit bats also reside on Aguiguan and travel to Tinian to forage (Cruz et al. 1999, 2000, 2002). In June 2005, approximately five Mariana fruit bats were seen in the cliff-line forest during a routine forest bird survey of the Maga bird transect (Navy 2008a). Because of the few numbers of bat observations and the likelihood that Mariana fruit bats observed on Tinian are not residents, the Mariana fruit bat should be considered incidental on Tinian. Noise as a stressor for Mariana fruit bats on Tinian and Saipan are considered negligible.

The Rota International Airport is adjacent to foraging habitats for the Mariana fruit bat. Combat search and rescue training occasionally occur at the airport. This training activity, however, is generally confined to the airfield where fruit bats are unlikely to occur. Trainings may also occur in open areas in coordination with local authorities. The likelihood for aircraft strike during combat search and rescue training should be considered extremely low because of the infrequent occurrence of the training activity and the locations of where these training activities are actually scheduled.

On Rota, aircraft noise would be generated by helicopters during combat search and rescue training activities and may affect the Mariana fruit bat. Typically, the Navy uses H-60 helicopters to practice day or night rescues of personnel in a simulated hostile area with the

expectation of combat resistance. Crews typically include Naval special warfare personnel or combat trained personnel with rescue swimmer and medical qualifications. This activity is mostly restricted to the Rota International Airport; however, other locations may be used in coordination with local authorities (e.g., Rota's mayor office). Helicopters may also transit out to sea for rescue swimmer training.

Mariana fruit bats are generally more active at night (a primary time for foraging when bats would fan out over Rota from roost locations in the limestone forests of the Sabana Plateau). Because suitable foraging habitat is adjacent to the Rota International Airport, helicopter noise may affect the Mariana fruit bat. With low-level helicopter flights, there is also a potential for aircraft strike of Mariana fruit bats. Adverse effects associated with this training activity are anticipated to be insignificant because of the infrequent use of the Rota International Airport and the even more infrequent low light exercises associated with this training activity. The potential for invasive species introductions into Rota's port facility and airport are addressed through exercise specific interdiction plans and standard operating procedures.

The Navy recognizes the potential for catastrophic effects on wildlife on Rota, Tinian, and Saipan resulting from the accidental introduction of brown treesnakes or other vertebrate predators. Accidental introductions of potentially invasive pests and plants could establish populations and further degrade habitats on these islands. Rota is of particular concern because of close proximity and shorter transit times from Guam and high quality habitats located throughout the island. Figure 2-6 shows a conceptual model of potential pathways of invasive species introductions to Rota, Tinian, and Saipan. These islands are linked together and to Guam by marine and air transportation routes that support military training activities.

The Navy's strategy to reduce, minimize, or eliminate species from potential introduction pathways includes the identification of critical control points. Accordingly, the Navy designs and implements exercise-specific interdiction implementation plans, in accordance with Navy policy directives and previous consultation requirements. The Navy also coordinates with local stakeholders (e.g., CNMI Division of Fish and Wildlife and U.S. Department of Agriculture Wildlife Services) to conduct redundant inspections of cargo, equipment, and material as required for specific exercises.

Based on the above information and the findings in the Environmental Baseline section for the Mariana fruit bat, the Service finds that the proposed action is likely to adversely affect the foraging and roosting behavior of the fruit bat on Rota as a result of noise caused by training activities based out of Rota International Airport. However, these adverse effects are not anticipated to significantly disrupt fruit bat foraging and roosting behavior to an extent that is reasonably certain to cause injury or death of the affected bat(s) because the affected bats are likely to shift their foraging and roosting sites away from areas used for the training activities.

FDM

The BA for the MITT program includes the following discussion on pages 81-83, and 85 regarding the effects of the MITT program on the fruit bat on FDM:

Mariana fruit bats on FDM may be transient bats from other islands, and/or the island may support a small resident population. The limited forest structure and composition currently

found on FDM may support a small number of year-round residents. Natural resource experts expressed concern that volcanic eruptions could displace fruit bats to other islands (e.g., from Anatahan to FDM), thereby exposing an increased number of bats to potential impacts of military training on FDM (Service 2006a, 2010).

Mariana fruit bats are expected to occur north of the no-fire line within the relatively more intact forests that remain on FDM. Therefore, the likelihood of munitions strike of Mariana fruit bats is considerably reduced, but not negated, because the area north of the no-fire line is not targeted. Since the 2010 Biological Opinion was issued, training impacts (e.g., bomb craters, destroyed targets) have been observed within the no targeting area proving that despite best efforts, exercises sometimes miss their targets.

Helicopter landings and approaches would occur in areas that may support Mariana fruit bats on FDM. The vegetation structure north of the no-fire line within the special use area contains higher stature foraging and roosting trees relative to the impact areas outside of the special use area. The Proposed Action includes 18 direct action-type training activities on FDM, which is an increase from 3 over previous training requirements. Mariana fruit bat behaviors in response to an approaching helicopter may include flushing and flying away from the sound source, or if in air, flying away from the sound source. Alternatively, roosting bats may not exhibit any behavioral response. These behavioral responses may reduce the likelihood of aircraft strike of Mariana fruit bats.

Mariana fruit bats transiting from other islands through FDM or resident bats on FDM are likely limited to the more intact forested portions north of the no-fire line. Therefore, bats that transit between other islands and/or resident bats will likely continue to have a foraging base on FDM. In this location, Mariana fruit bat foraging habitat may be degraded through accidental target misses and impacts north of the no targeting line.

Catastrophic events within the Mariana archipelago may temporarily cause populations of fruit bats to fluctuate on different islands, although movement between islands seems to be a natural occurrence. These events may result from typhoons, poaching, or volcanic eruptions. Catastrophic events and other factors may cause Mariana fruit bat populations on FDM to temporarily increase, thereby exposing transient or resident bats to potential harassment and harm associated with live-fire training. Mariana fruit bats can be assumed to utilize FDM as a resting point for longer inter-island movements. Because of the location of likely foraging and roosting locations (located in the northern portion of the island north of the "no fire zone"), impacts associated with wildfires occurring primarily in the central portion of the island would be unlikely. The likelihood of a wildland fire spreading north out of the impact zones into more intact forests on the northern portion of the island cannot be negated; however, factors such as a relatively higher fuel moisture content and mesic conditions in the higher stature vegetation may limit the spread of fires.

The Navy recognizes the potential for catastrophic effects on wildlife on FDM resulting from the accidental introduction of brown treesnakes or other vertebrate predators. Accidental introductions of potentially invasive pests and plants could establish populations and further degrade habitats on FDM. Figure 2-6 shows a conceptual model of potential pathways of invasive species introductions to FDM. The only military activities that could introduce invasive species to FDM are activities requiring aircraft landings. Military boats do not come

ashore at FDM. Helicopters that land on FDM typically embark from Guam or Saipan, but some helicopters may originate from Tinian.

The Navy's strategy to reduce, minimize, or eliminate species from potential introduction pathways includes the identification of critical control points. Accordingly, the Navy has designed and implemented inspection and interdiction procedures specific to FDM, in accordance with Navy policy directives and previous consultation requirements. As stated in Section 1.2.3.1 (Brown Treesnake Interdiction and Control) Section 1.4.1.2 (Conservation Measures on Farallon de Medinilla), all aircraft and equipment originating from Guam and landing on FDM must undergo brown treesnake inspection procedures prior to departing Guam. Appendix B (Brown Tree Snake Control and Interdiction Requirements) of this BA is included in COMNAVMARIANASINST 3500.4A, adherence to this instruction is mandatory for training within the Mariana Islands.

Based on the above information and the findings in the Environmental Baseline section for the Mariana fruit bat, the Service finds that the proposed action is likely to adversely affect the foraging and roosting behavior of the fruit bat on FDM as a result of noise, percussive force, and wildfires caused by training activities. There is a high potential for these effects, at times, to injure or kill affected fruit bats, especially considering the increased training activity on FDM and project duration. However, given the low number of fruit bats that occur on FDM, the proposed action is not considered a significant impact to the Mariana fruit bat at the rangewide scale.

CUMULATIVE EFFECTS

Cumulative effects include the effects of future State, tribal, local or private activities that are reasonably certain in the action area considered in this Opinion. Future Federal actions that are unrelated to the proposed action are not considered in this section because they require separate consultation pursuant to section 7 of the ESA.

Recreation and tourism occur within the Military Lease Area on Tinian. In general, the tourists are bused to historical sites, while some use rental cars. These tourism activities are not anticipated to result in effects to the Micronesian megapode or Mariana fruit bat as the species are transient on Tinian and the majority of the sites are not in habitats that would be used by the megapode or fruit bat. There are no historical landmarks in the area where fruit bats or megapodes were last detected.

Homesteads, private development, tourism, and unauthorized clearings are likely to occur within the timeframe of this action within the Marpi Maneuver Area on Saipan. This clearing and development are likely to further reduce the amount and quality of megapode habitat in the area. Natural disasters, such as typhoons, also occur regularly on Saipan further damaging habitat. However, no nesting habitat is expected to be lost.

CONCLUSION

After reviewing the current status of the Mariana fruit bat and the Micronesian megapode, the environmental baseline for the action area, the effects of the proposed action and cumulative

effects, it is the Service's biological opinion that the Navy's proposed action is not likely to jeopardize the continued existence of the Mariana fruit bat and the Micronesian megapode.

The Service reached these findings based on the following reasons:

Activities under the proposed action will not remove habitat essential or important to the conservation of these species on Guam, Rota, Tinian, and Saipan. The proposed action is likely to cause the destruction and degradation of habitats utilized by small numbers of the fruit bat and the megapode on FDM. However, this island is not considered essential to the recovery of the megapode.

On Guam, proposed training areas avoid sites known to support Mariana fruit bat roosts, and proposed conservation measures related to aircraft use and ground maneuvers are likely to minimize noise, strike potential, physical disturbance, and habitat degradation impacts on the fruit bat. On Rota, the bat(s) that occur near the airport would likely shift their foraging and roosting sites away from proposed training activities at the airport. On Tinian and Saipan, proposed training activities avoid areas known or likely to be occupied by the fruit bat.

The Micronesian megapode is currently considered to be extirpated from Rota. On Tinian and Saipan, few proposed training activities are expected to occur in habitats likely to be occupied by the Micronesian megapode.

The potential for the proposed action to cause the inter-island transport and introduction of invasive species is minimized by proposed measures to develop and implement training exercise-specific interdiction plans, and to conduct redundant inspections of cargo, equipment, and other materials associated with specific training exercises. The Service is also relying on the Navy's commitment to prepare, along with other stakeholders, a program to implement the Regional Biosecurity Plan for Micronesia and Hawaii.

INCIDENTAL TAKE STATEMENT

Section 9 of the ESA and federal regulation pursuant to section 4(d) of the ESA prohibit the take of endangered and threatened species, respectively, without special exemption. Take is defined as to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture or collect, or to attempt to engage in any such conduct. Harm is further defined by the Service to include significant habitat modification or degradation that results in death or injury to listed species by significantly impairing essential behavioral patterns, including breeding, feeding, or sheltering. Harass is defined by the Service as intentional or negligent actions that create the likelihood of injury to listed species to such an extent as to significantly disrupt normal behavior patterns which include, but are not limited to, breeding, feeding or sheltering. Incidental take is defined as take that is incidental to, and not the purpose of, the carrying out of an otherwise lawful activity. Under the terms of section 7(b)(4) and section 7(o)(2), taking that is incidental to and not intended as part of the agency action is not considered to be prohibited taking under the ESA, provided that such taking is in compliance with the terms and conditions of this Incidental Take Statement.

The measures described below are non-discretionary, and must be undertaken by the action agencies for the exemption in section 7(o)(2) to apply. The action agencies have a continuing duty to regulate the activities covered by this Incidental Take Statement. If the action agencies fail to assume and implement the terms and conditions of this Incidental Take Statement, the protective coverage of section 7(o)(2) may lapse. In order to monitor the impact of incidental take, the action agencies must report the progress of the action and its impact on the species to the Service as specified in this Incidental Take Statement in accordance with the implementing regulations for section 7 at 50 CFR §402.14(i)(3).

Amount or Extent of Take Anticipated

Two pairs of the Micronesian megapode are likely to be killed every year on FDM as a result of bombing, gunnery, and missile exercises implemented under the MITT program. One Mariana fruit bat is likely to be killed every five years on FDM as a result of bombing, gunnery, and missile exercises implemented under the MITT program.

Effect of the Take

In the accompanying Opinion, the Service determined the above level of anticipated take is not likely to result in jeopardy to the Micronesian megapode and the Mariana fruit bat.

Reasonable and Prudent Measures

The Service believes the following reasonable and prudent measures (RPMs) are necessary and appropriate to further minimize the effect of take on the Micronesian megapode and to monitor the impacts of take of the Micronesian megapode and Mariana fruit bat on FDM caused by the proposed action.

1. Minimize the effect of take from training and range maintenance to Micronesian megapodes.

2. The baseline condition for the Micronesian megapode and Mariana fruit bat shall be tracked to ensure that proposed minimization measures on FDM are implemented and to ensure no unauthorized take occurs.

Terms and Conditions

In order to be exempt from the prohibitions of section 9 of the ESA, the DoD action agencies for the MITT program must comply with the following terms and conditions that implement the above RPMs. These terms and conditions are non-discretionary and must be implemented.

1.1 The DoD action agencies for the MITT program shall complete an island-wide ungulate eradication on Aguiguan (Goat Island). This action will benefit the Micronesian megapode by increasing vegetation on the island and creating suitable habitat, and will minimize the effects of take from the proposed action. This eradication will occur within six years of the issuance date of the Biological Opinion.

2.1. The DoD action agencies for the MITT program shall establish a formal protocol for the timing and implementation of megapode surveys on FDM in coordination with and the approval of the Service within 180 days of the issuance date of the accompanying Opinion.

2.2. The DoD action agencies for the MITT program shall conduct surveys for the Micronesian megapode along trails or paths that have been established during target refurbishment and operational range clearance activities. The results of these surveys shall be used as an index of megapode population change over time due to take impacts on FDM caused by the proposed action. Mariana fruit bats observed during surveys shall be recorded.

2.3. The DoD action agencies for the MITT program shall establish an appropriate monitoring protocol for ground surveys in conjunction with range maintenance activities on FDM to monitor megapode and bat habitat changes over time on FDM, and for reporting the results of this analysis in coordination with and the approval of the Service within 180 days of the issuance date of the accompanying Opinion.

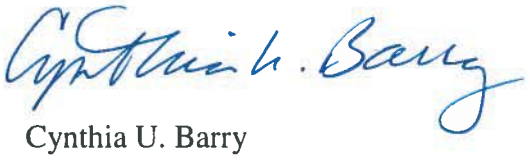
2.4. The DOD action agencies for the MITT program shall provide the results of each survey and the change in habitat on FDM and concisely discuss the successes and challenges of implementing all the avoidance, minimization and conservations measures and terms and conditions listed in the Biological Opinion in an annual report submitted to the Service. The report also shall include the changes to the no impact area as a result of the accidental bombing and destroyed targets entering this area. The report is due at the end of the calendar year, December 31st, for the life of the project.

CONSERVATION RECOMMENDATIONS

Section 7(a)(1) of the ESA directs Federal agencies to utilize their authorities to further the purposes of the ESA by carrying out conservation programs for the benefit of endangered and threatened species. Conservation recommendations are discretionary agency activities to minimize or avoid adverse effects of a proposed action on listed species or critical habitat, to help implement recovery plans, or to develop information.

The Service believes the following conservation action may facilitate further conservation of listed species within the Action Area:

1. The Navy is committed to coordinating with the Service and other stakeholders on the development of a programmatic action to implement the Regional Biosecurity Plan for Micronesia and Hawaii, inclusive of an effective rapid response plan (D. Schregardus, Deputy Assistant Secretary of the Navy, Environment, pers. comm. to Theresa Rabot, Service, Assistant Regional Director, Ecological Services, Region 1). The Service believes that effective rapid response is predicated on early detection of introduced species based on an adequate monitoring program. The Service supports and recommends that the DoD action agencies for the MITT program work aggressively with the Service and other stakeholders to develop and implement the above programmatic action region-wide in as timely a manner as possible.



2. The Service recommends that the DoD agencies implementing the MITT program place a high priority on developing and implementing biosecurity monitoring measures in a timely manner that are adequate to detect an incipient population of the BTS that is introduced on or adjacent to lands used for training activities as a result of the proposed action. Such measures should also be part of the program discussed above for implementing the Regional Biosecurity Plan for Micronesia and Hawaii.

REINITIATION NOTICE

This concludes formal consultation on the proposed Project described in your Assessment. As provided in 50 CFR § 402.16, re-initiation of consultation is required where discretionary Federal agency involvement or control over the action has been maintained (or is authorized by law) and if: (1) the amount or extent of exempted incidental take is exceeded; (2) new information reveals effects of the agencies' action that may affect listed species or critical habitat in a manner or to an extent not considered in this opinion; (3) the agency action is subsequently modified in a manner that causes an effect to listed species or critical habitat that was not considered in this Opinion; or (4) a new species is listed or critical habitat designated that may be affected by the action. When consultation is reinitiated, the provisions of section 7(d) of the ESA apply.

This concludes formal consultation on the proposed MITT program. If you have any questions regarding this Opinion, please contact Kristi Young of the Service's Pacific Islands Fish and Wildlife Office at (808) 792-9400.

Sincerely,

Cynthia U. Barry
Acting Field Supervisor

Appendix A. Increase in proposed MITT Program training activities currently being conducted under the MIRC Program.

2 ASSESSMENT OF MILITARY TRAINING ACTIVITIES ON GUAM

2.1 DESCRIPTION OF THE PROPOSED ACTION AND ACTION AREA

1.1.1 PROPOSED ACTIVITIES ON GUAM

Most of the land training activities considered in this BA are expected to occur on Guam. The land training areas are owned either by the U.S. Navy or the U.S. Air Force. Guam offers a variety of land training environments, including amphibious landing sites (within Naval Base Guam Main Base), field training exercises and land navigation training (portions of Andersen AFB, such as Northwest Field), airfield expeditionary and seizure trainings (Northwest Field and Naval Base Guam Main Base), land navigation areas (within the Naval Base Guam Munitions Site), and urban warfare, counter-terrorism, and humanitarian training areas on all military training areas on Guam.

Table 2-1 presents a list of training activities by warfare area, proposed location of the training activity, the number of training activities previously analyzed in the 2010 MIRC Biological Opinion, and the proposed increase in certain activities on Guam. Not all activities listed in Table 2-1 are proposed for increases (the activities proposed for increases are shown in bold). Most of the activities proposed for increases on Guam would occur on previously disturbed and developed areas, hardened surfaces, and urban warfare infrastructure (e.g., breacher houses and military operations on urban terrain [MOUT]) that are outside of habitat areas for ESA-listed species. Activities such as land navigation and field training exercises are not proposed for increases.

Table 2-1: Typical Training Activities in the Action Area on Guam

Activity Name	Location	Baseline Number of Activities (per year)	Proposed Number of Activities (per year)
Strike Warfare (STW)			
Combat Search and Rescue (CSAR)	**Airfields on Naval Base Guam and Andersen AFB (Northwest Field)**	**60**	**80**
Amphibious Warfare (AMW)			
Amphibious Assault	**Naval Base Guam Main Base landing sites**	**4**	**6**
Amphibious Raid	**Naval Base Guam Main Base landing sites**	**2**	**6**
Urban Warfare Training	**Naval Munitions Site, Andersen AFB, Andersen South, Naval Base Guam Barrigada, Navy Base Guam Telecommunications Site**	**17**	**36**

Table 2-1: Typical Training Activities in the Action Area on Guam (continued)

Activity Name	Location	Baseline Number of Activities (per year)	Proposed Number of Activities (per year)
Noncombatant Evacuation Operations	**Naval Munitions Site, Andersen AFB, Naval Base Guam Barrigada, Navy Base Guam Telecommunications Site**	**2**	**5**
Naval Special Warfare (NSW)			
Personnel Insertion/Extraction	**Naval Munitions Site, Andersen South, beach locations at Andersen AFB (Tarague Beach), Naval Base Guam Main Base, and Naval Base Guam Telecommunications Site**	**150**	**240**
Parachute Insertion	**Various drop zones on Navy lands**	**12**	**20**
Embassy Reinforcement	Naval Munitions Site, Andersen AFB, Andersen South, Naval Base Guam Barrigada, Navy Base Guam Telecommunications Site	50	50
Direct Action (Combat Close Quarters)	**Naval Munitions Site, Andersen AFB, Andersen South**	**40**	**72**
Direct Action (Breaching)	**Naval Munitions Site, Andersen AFB, Andersen South**	**40**	**72**
Intelligence, Surveillance, Reconnaissance (ISR)	Naval Munitions Site, Andersen AFB, Andersen South	16	16
Urban Warfare Training	**Naval Munitions Site, Andersen AFB, Andersen South**	**8**	**18**
Other Training Activities			
Maneuver (Convoy, Land Navigation)	Naval Munitions Site, Andersen AFB, Andersen South	16	16
Water Purification	**Naval Base Guam**	na	16
Field Training Exercise	Naval Munitions Site, Andersen AFB, Andersen South	100	100
Force Protection	Naval Munitions Site, Andersen AFB, Andersen South	75	75
Anti-terrorism	Naval Munitions Site, Andersen AFB, Andersen South	80	80
Seize Airfield	Airfields on Naval Base Guam and Andersen AFB (Northwest Field)	12	12
Airfield Expeditionary	Airfields on Naval Base Guam and Andersen AFB (Northwest Field)	12	12
Land Demolitions (Improvised Explosive Device Discovery/Disposal)	Hardened-surface airfields on Naval Base Guam and Andersen AFB (Northwest Field)	120	120
Land Demolitions (Unexploded Ordnance) Discovery/Disposal	**Explosive ordnance units conduct disposal of unexploded ordnance. Training is incidental to the emergency disposal of unexploded ordnance. Disposal occurs at Andersen AFB EOD Range. Emergency detonations may occur at Andersen AFB EOD Range and Naval Munitions Storage.**	**200**	**236**

Notes:
1. Activities in **bold text** are activities that are proposed to increase in the number of occurrences per year relative to the number of exercises previously analyzed in the 2010 MIRC Biological Opinion. Activities that are not in bold text will not increase in occurrences per year.
2. AFB = Air Force Base; na = not applicable, not analyzed previously in the 2010 MIRC Biological Opinion

Table 3-1: Typical Training Activities in the Action Area on Rota, Tinian, and Saipan

Activity Name	Location			Baseline Number of Activities	Proposed Number of Activities
	Rota	Tinian	Saipan		
Strike Warfare					
Combat Search and Rescue	X	X	-	60	80
Amphibious Warfare					
Amphibious Assault	-	X	-	4	6
Amphibious Raid	-	X	-	2	6
Urban Warfare Training	-	X	-	17	36
Noncombatant Evacuation Operations	X	X	-	2	5
Naval Special Warfare					
Personnel Insertion/Extraction	X	X	-	150	240
Parachute Insertion	X	X	-	12	20
Embassy Reinforcement	X	X	-	50	50
Direct Action (Combat Close Quarters)	-	X	-	40	72
Direct Action (Breaching)	-	X	-	40	72
Intelligence, Surveillance, Reconnaissance	X	X	X	16	16
Urban Warfare Training	X	X	X	8	18
Other Training Activities					
Maneuver (Convoy, Land Navigation)	-	X	X	16	16
Water Purification	X	X	X	NA	16
Field Training Exercise	X	X	X	100	100
Force Protection	X	X	-	75	75
Anti-terrorism	X	X	-	80	80
Seize Airfield	X	X	X	12	12
Airfield Expeditionary	X	X	X	12	12
Land Demolitions (Improvised Explosive Device Discovery/Disposal)	-	X	-	120	120
Land Demolitions (Unexploded Ordnance) Discovery/Disposal	-	X	-	200	236

4 ASSESSMENT OF MILITARY TRAINING ACTIVITIES ON FARALLON DE MEDINILLA

4.1 DESCRIPTION OF THE PROPOSED ACTION AND ACTION AREA

4.1.1 PROPOSED ACTIVITIES DESCRIPTION

4.1.2 FDM is the DoD's only U.S.-controlled range available for live-fire training for forward deployed military forces. The air and sea space surrounding FDM provides sufficient room for the many different attack profiles necessary to replicate training opportunities in the CNMI. FDM presents a unique opportunity to maintain capability and proficiency in precision-guided weapons and specific target engagement. The range supports strike warfare exercises (air to ground bombing exercises, air to ground gunnery exercises, and missile and rocket exercises), amphibious warfare activities (fire support exercises from cruisers and destroyers), and Naval special warfare activities (direct action exercises using tactical air control).

Number of Activities

Table 4-1 lists each training activity, the baseline number of activities and ordnance amount currently approved for FDM, and the proposed changes in frequency and ordnance use of the island.

Table 4-1: Baseline and Proposed Training Activities on Farallon de Medinilla

Activity Name	Baseline Activities	Proposed Activities
	Number of Exercises (per year)	Number of Exercises (per year)
Strike Warfare		
Bombing Exercise Air-to-Ground	1,300	2,300
Gunnery Exercise Air-to-Ground	22	96
Missile Exercise	60	85
Amphibious Warfare		
Fire Support Exercise-Land Based Target (FIREX [Land])	8	10
Naval Special Warfare		
Direct Action (Tactical Air Control Party)	3	18

Ordnance Expenditures The FDM range is operated in accordance with the terms and conditions specified in the 2010 Biological Opinion (U.S. Fish and Wildlife Service 2010), for the take of Micronesian megapodes on FDM.

Appendix B. MIRC/MITT Conservation Measures

MIRC/MITT Conservation Measures
February 20, 2015

The following list of Conservation Measures (CM) serves to consolidate those CMs offered in Navy's August 2014 BA for the action, the US Fish and Wildlife Service's (Service) draft Biological Opinion (BO) transmitted to the Navy on December 18, 2014, Appendix B of that draft (the MIRC BO and MITT BA Conservation Measures comparison table, as updated December 15, 2014) and December 2014 agreements between Navy and the Service regarding the description of the action on Tinian specific to beach use and potential effects to sea turtles.

This list replaces the December 18, 2014 draft BO Appendix B. It allows participating DoD Branches and units to more efficiently reference them to ensure their implementation.

I. CONSERVATION MEASURES APPLICABLE THROUGHOUT THE ENTIRE ACTION AREA

BIOSECURITY

Brown Treesnake (BTS) Interdiction and Control

1. Upon completion of the MIRC Reinitiation BO and other pending consultations, Navy will update the COMNAVMARIANASINST 3500.4A to reflect the language contained in these Biological Opinions applicable to range users. Navy will also finalize a new Joint Region COMNAVMAR Brown Treesnake instruction, which will contain the Brown Treesnake Control and Interdiction Requirements. These efforts shall be prepared in coordination with the Service and other stakeholder agencies.

2. Training activities will undergo a pathway risk analysis as a tool to improve programmatic efficiency while preventing the spread or introduction of BTS.

3. The Navy, in compliance with Public Law 110-417, [Division A], title III, Section 316, October 14, 2008, 122 Statute 4410 and per Department of Defense (DoD) Transportation Regulations, Chapter 505 protocols, is committed to implementing 100% inspection of all aircraft and all cargo/equipment leaving Guam via vessel or aircraft for an off-island destination with trained brown treesnake personnel and qualified canine detection teams. The skills and standards required to certify personnel, including canine inspection teams, as "qualified" will be agreed upon mutually by DoD and the Service. These teams may be supplemented with qualified personnel to meet 100 percent inspection goals for training activities.

a. Missed Brown Treesnake Inspections - In the event military units, vehicles, or equipment accidentally leave Guam without inspection, as soon as possible, the Navy will notify the qualified brown treesnake interdiction program and the destination port or airport authorities. The Navy will work with the destination authority(ies) to resolve the issue. Urgency of notification is a priority so that rapid response or other actions can be implemented to reduce risk, if warranted.

b. Tactical Approach Exercises/Events - To the maximum extent practicable, the Navy will route inbound personnel and cargo for tactical approach exercises (that require an uninterrupted flow of events) directly to CNMI training locations to avoid Guam seaports and airfields to the extent possible. If Guam cannot be avoided for tactical approaches, the Navy will work with the U.S. Fish and Wildlife Service to

identify and implement appropriate interdiction methods at the receiving port (Rota, Saipan or Tinian). Methods may include redundant inspections or other interdiction actions, such as multiple inspections or barrier use on Guam. In addition, tactical approach exercises will involve only cargo/equipment that has not originated from areas containing a brown treesnake population or will be 100 percent inspected by qualified brown treesnake canine detection programs.

c. Administrative/Logistic Movements - The Navy is committed to implementing redundant inspections after discussions with appropriate stakeholders. Redundant inspections include inspections on Guam and at the receiving ports (Rota, Saipan or Tinian) for administrative and logistical movements within the MITT action area that do not require a tactical approach to complete the training requirements. It is anticipated that redundant inspections would utilize existing quarantine and inspection protocols at receiving ports in the CNMI to the extent possible. However, should inspection coverage be inadequate, the Navy will provide inspection teams to fully implement quarantine and inspection protocols. Appropriate stakeholders include, but are not limited to the U.S. Fish and Wildlife Service to ensure the inspections are adequate to reduce risks to trust resources, receiving jurisdictions and their supporting agencies with expertise in invasive species control, and other inspection authorities as needed to ensure inspection methods are current and revised as new techniques, technology, or data become available.

d. Movements Involving Farallon de Medinilla (FDM) - The Navy will consider all movements between Guam and FDM as tactical in nature and work with appropriate stakeholders to determine the appropriate interdiction methods required for aircraft, personnel, and equipment/gear movements. All aircraft and equipment/gear will be 100 percent inspected prior to departing Guam. Additional interdiction measures on Guam may be required after discussions with appropriate stakeholders. Training operations that go from Guam to Saipan and then FDM will require canine inspection on Saipan or other BTS inspection as mutually agreed upon by the DoD and the Service. For training that starts on Guam and goes directly to FDM, visual inspections for BTS will be conducted by military or UXO personnel upon arrival on FDM.

4. The Navy will establish snake-free quarantine areas (barriers) as deemed necessary by the Navy and U.S. Fish and Wildlife Service for cargo/equipment traveling from Guam to CNMI and locations outside of the MITT action area. Barriers will be used if the volume of cargo/equipment/vehicle movement out-paces the available canine inspection capacity or BTS quarantine capacity. The snake-free quarantine areas will be subject to: (1) multiple day and night searches with appropriately trained interdiction canine teams, (2) snake trapping, and (3) visual inspection for snakes. Standard operating procedures will be developed based on the barrier size needed for the training event(s). Temporary barriers will be constructed and maintained in a manner that assures the efficacy of the barrier and that staff maintaining and constructing the temporary barriers will receive training related to this activity prior to construction and operation. Barrier specifications as well as the qualifications of BTS barrier maintenance and management staff will be mutually agreed upon by DoD and the Service.

5. Navy will (1) coordinate closely with the Service1 and the CNMI Department of Land and Natural Resources staff on planning for training activities in the CNMI; (2) coordinate with the other DoD action agencies implementing the MITT program and the Service to identify the inspection and interdiction requirements for MITT program-related training activities, including the number of trained quarantine

1 Currently, the Service point-of-contact (POC) for these planning activities is the CNMI Brown Tree Snake Program Coordinator (Coordinator). If the agency affiliation of that Coordinator changes, the Service shall formally designate a new Service POC and advise the DON and other DOD action agencies associated with the MITT Program within 10 working days.

officers and canine detection teams required to ensure that the inspection and interdiction requirements for MITT program-related training activities can be met; (3) coordinate with the Service on the inspection and interdiction requirements identified by the Navy prior to the implementation of the exercise or training activity; and (4) identify the support that the Navy will need to provide for the inspections and develop plans to ensure that inspection personnel are available and all requirements are met.

6. Navy will utilize ongoing adaptive management to improve methods for BTS rapid response, including detection of low-density snake populations using all technologies as they become available. The Navy will annually review BTS rapid response needs with the Service to mutually determine if refined methods need to be implemented; the Navy will support such refinement based on that mutual agreement. Support for this adaptive management approach will include financial support subject to Congressional funding guidelines and restrictions. All parties acknowledge financial support is subject to the availability of funds, and no provision herein shall be interpreted to require obligation of payment of funds in violation of the Anti-Deficiency Act, 31 U.S.C Section 1341

7. MITT action proponents will provide support for BTS rapid response associated with a BTS sighting with the JRM AOR related to MIRC training activities subject to this consultation.

8. The Navy will provide brown treesnake awareness briefings for all military and contractor personnel prior to all MITT training activities. Brown treesnake awareness briefings will be scaled to the type of training activity to take place. Awareness materials may consist of a brown treesnake educational video and distribution of brown treesnake information and personal inspection guidelines. Awareness briefs will emphasize that brown treesnake awareness must extend through the chain of command from the Commanding Officer to the individual military service member.

9. Joint Region Marianas (JRM) will assure that "Area Training" coordinates meetings for BTS interdiction on all training activities for the training execution phase and an after-action review phase. If a snake is found during training, the Navy policy is to kill the snake and is reported to Navy Environmental Staff.

10. The Navy will invite the Service to participate in the development of regional standard operating procedures and exercise planning to better meet BTS management needs associated with MITT training.

Other Invasive Species

11. Prior to each exercise that involves the movement of equipment and troops between islands, a pathway risk analysis will be conducted and biosecurity protocols confirmed by the DoD (JRM). Implementation of biosecurity protocols will be a requirement for training. An adaptive management review of risk analyses and biosecurity protocols will be conducted periodically with the Service. Initially, this adaptive management review will include the development of Standard Operating Protocols (SOPs) for biosecurity by the DoN in support of training activities covered under the MITT program. These DoN biosecurity SOPs will be reviewed by the Service when initially developed. Once the MITT program is implemented, MITT program-related SOPs will be reviewed with the Service annually.

12. In coordination with the Service, the DoD action agencies implementing MITT activities will establish a contractual agreement for adequate rapid response capabilities with appropriate agencies having invasive species rapid response expertise and technology within three months of the Service's issuance of this Biological Opinion. The contracted services will focus on control and eradication of introduced

non-established, non-native invasive species sighted in the vicinity of: (1) DoD MITT training areas, and (2) DoD areas and facilities used for the staging, storage and movement of MITT personnel, cargo, and MITT-associated vehicles (e.g., planes, trucks, and vessels). Priority should be given to non-native invasive species that pose a high risk of being transported elsewhere due to MITT-related training actions. This arrangement will be in place until superseded by a regional rapid response plan2. Monitoring will consist of the established protocols for USDA inspections, personnel awareness during pre-event preparations, and self-inspections. As noted above, an adaptive management review of risk analyses and biosecurity protocols will be conducted periodically with the Service.

13. All personnel involved in MIRC/MITT training will be responsible for conducting self-inspections to avoid potential introductions of invasive species to Guam and the CNMI. Troops will inspect all gear and clothing (e.g., boots, bags, weapons, and clothing) for soil accumulations, seeds, invertebrates, and vertebrates).

14. Navy will adhere to AFPMB Technical Guide 31 protocols on vehicle/equipment washdown procedures and other APHIS PPQ inspection procedures for deployments and redeployments.

EROSION CONTROL

15. The Navy will locate ground-disturbing training activities on previously disturbed sites whenever possible.
16. The Navy will ensure that all training areas, including transit routes necessary to reach training areas, are clearly identified or marked. Vehicular activities will be restricted to designated and previously identified areas.

17. The Navy will continue to control erosion through the "Site Approval Process," whereby the Navy environmental program reviews each proposed project for its erosion potential and involves the designated installation Natural Resource Specialist in the process.

18. The Navy will continue to manage erosion in accordance with the applicable storm water pollution prevention plan at each training location.

19. The Navy will prohibit off-road vehicle use except in designated off-road areas or on established trails.

20. The Navy will comply with existing policies and management activities to conserve soils, including requirements and restrictions outlined in the Marianas Training Handbook.

II. FARALLON de MEDINILLA

21. The Navy will continue to implement targeting and access restrictions, such as: (1) no targeting of the northern Special Use Area (north of the No Fire Line) and no targeting of the narrow land bridge, (2) only targeting Impact Areas 1, 2, and 3 during air-to-ground bombing exercises and air-to-ground missile

2 The regional rapid response plan discussed refers to the full implementation of a comprehensive Emergency Response Plan for Guam and the CNMI in association with the Regional Biosecurity Plan (RBP) for Micronesia and Hawaii. The RBP is discussed further in the MIRC re-initiation / MITT Biological Opinion.

and gunnery exercises; Impact Area 1 (closest to the northern Special Use Area) is for inert ordnance only, and (3) personnel are not authorized on FDM without approval from JRM Operations.

22. Live cluster weapons/scatterable munitions, fuel air explosives, incendiary munitions, depleted uranium rounds, or bombs greater than 2,000 pounds will be prohibited. It should be noted that some spotting charges use small amounts of phosphorous but are not main constituents of munitions dropped on FDM. In addition, smoke markers will be used during some direct action activities for targeting.

23. Nesting sea turtles are not expected; however, it is possible that a sea turtle may be basking on beaches or resting in holes or caves. If a sea turtle is seen on a beach by participating aircraft, training will be altered until the sea turtle leaves the beach and nearby waters.

III. SAIPAN

24. Training in the Marpi Maneuver Area is expected to be infrequent and limited to pedestrian land navigation training.

a. Training will be limited to open areas (i.e., grasslands; no forest or mixed shrub and scrub habitats) to minimize impacts to nightingale reed-warblers, Mariana fruit bat, and Micronesian megapodes.

b. There will be no digging in the soil or cutting of vegetation along the southern border of the Marpi Maneuver Area in the mixed limestone forest. No ground disturbance or vegetation removal of any kind is permitted in this area to avoid impacts to the Micronesian megapode and Mariana fruit bat. Vegetation removal would be limited to the maintenance of existing bivouac areas. No new bivouac areas are proposed. Maneuver units will remain tactical and not establish support camps. This measure is designed to minimize potential impacts associated with ground maneuvers on the Micronesian megapode No habitat will be removed for any training activity on Saipan.

c. Smoking is not permitted during training activities and fire-safe-portable receptacles for cigarette butts are used during periods of rest between training activities. No fires are permitted during bivouac activities.

d. If other areas are needed for training, the Navy will contact the Service regarding the need for reinitiation of this biological opinion.

e. All training activities that involve ground maneuvers in the Saipan Marpi Maneuver Area will be consistent with the fire management plan included in COMNAVMARIANASINST 3500.4A.

25. JRM will coordinate with CNMI-DLNR to determine the latest species locations as necessary prior to training actions. If a training exercise cannot be modified to avoid impacts on listed ESA species, the Navy will contact the Service as required by Section 7 of the ESA prior to conducting the training exercise. If CNMI-DLNR is not able to assist with best available data or surveys, Joint Region Marianas will provide in-house or contracted subject matter experts to conduct surveys if necessary.

IV. TINIAN

Training Restrictions:

26. All training activities that involve ground maneuvers on Tinian Military Lease Area will be consistent with the fire management plan included in COMNAVMARIANASINST 3500.4A.

27. The Navy will locate ground-disturbing training activities on previously disturbed sites whenever possible. Training areas, including transit routes necessary to reach training areas will be clearly marked. On Tinian, vehicular activities will be restricted to designated and previously identified areas.

28. The Navy will implement training restrictions at Unai Chulu, Unai Babui, and Unai Dankulo to avoid and minimize effects to sea turtles:

a. Unai Chulu, Unai Babui, and Unai Dankulo will not be designated as landing zones for mechanized amphibious vehicles at this time. Should mechanized amphibious vehicles (AAV and LCAC) landings on those beaches become necessary, Navy will reinitiate consultation for those activities.

b. Biologists trained in identifying sea turtle nests will survey landing beaches no more than six hours prior to the first non-mechanized craft landing or use of other beach landing equipment that is part of a training event that requires use of the beach. Any potential sea turtle nests will be flagged and avoided by landing craft and personnel, vehicles (including non-mechanized water craft) and equipment. The buffer zone will have a radius of 6 meters (20 feet) from the edge of the nesting activity (area disturbed by the turtle) to ensure complete avoidance. Use of a beach monitor during the training event and turtle-friendly lighting will avoid impacts to nesting females.

c. If an active nest has been discovered, night-training will not occur after 50 days of incubation until the nest has hatched OR a buffer (9 meters [30 feet] wide) from the active nest to the water will be in place to avoid any potential impacts to sea turtle hatchlings trying to reach the ocean. If an active nest has been discovered, night-training will not occur once a prehatch hole is detected. (A pre-hatch hole indicates that the nest will hatch that evening.) Evening training may resume five days after the pre-hatch hole is discovered.

d. For any training on beaches at night during the sea turtle nesting season, only turtle-friendly lighting will be used. No lighting will be used in the vicinity of nests that are past 50 days of incubation.

29. Improvements to any beaches to facilitate training will be coordinated with the Service if the action may affect listed species.

30. On Tinian, Hagoi and adjacent areas are designated as a "No Training Area." No ground disturbance or vegetation removal of any kind is permitted in this area. This measure is designed to avoid impacts associated with ground training activities on the Mariana common moorhen. Training also does not occur in the Bateha or Mahalang wetlands areas.

31. Aircraft overflights are restricted over Tinian wetland areas (Hagoi, Mahalang, and Bateha). If aircraft must fly over wetlands during training exercises, the aircraft must maintain a minimum altitude of 1,000 feet (305 meters) AGL. This measure is designed to minimize visual and noise disturbance for Mariana common moorhens, and to reduce the potential for aircraft strike.

32. On Tinian, training does not occur in limestone forests, found within the Tinian MLA along ridgelines associated with Mount Lasso (see COMMNAVMARIANAS 3500.4A, Figure 5-2). This measure is designed to avoid impacts associated with ground training activities on the Micronesian megapode. Vegetation

removal would be limited to the maintenance of existing bivouac areas. No new bivouac areas are proposed. Maneuver units will remain tactical and not establish support camps. This measure is designed to minimize potential impacts associated with ground maneuvers on the Micronesian megapode.

33. Aircraft overflights are restricted over limestone forest areas of Tinian, which are found within the Tinian MLA along ridgelines in the Mount Lasso area. If aircraft must fly over limestone forests during training exercises, the aircraft must maintain a minimum altitude of 1,000 feet (305 meters) AGL. This measure is designed to minimize visual and noise disturbance of Micronesian megapodes and fruit bats and to reduce the potential for aircraft strike (see COMNAVMARIANASINST 3500.4A, Figure 5-2).

Fire Prevention: (See COMNAVMARIANASINST 3500.4A Table 5-1)

34. No live-fire or tracer rounds will be used on Tinian except with the use of bullet traps. Use of pyrotechnics, flares, blank fire, and other potential fire-starting activities must be conducted on existing cleared runways and in accordance with the Fire Prevention Plan. The area authorized for open fires and pyrotechnics is restricted to the North Field and West Field on hardtop surfaces only (except for actual emergency signaling).

35. Cooking by individuals is not authorized in outdoor training areas (except for heating tabs and mechanisms in "meals ready to eat"). Large scale training exercises may include field kitchens in North Field in areas authorized for open fire.

36. North Field's existing runways and taxiways act as fire breaks and fire access roads, and the vegetation is primarily characterized by tangantangan *(Leucaena leucocephala)* thickets. Standard Operating Procedures for all exercises include fire response measures that must be implemented.

37. To date, no wildland fire has been ignited from MIRC training activities on Tinian (or on other DoD lands in the Mariana Islands). However, to further minimize risk and augment military fire response efforts, the Tinian Fire Department maintains a 300-gallon pump truck and fire crew to respond to wildland fires. The Tinian Fire Department also maintains a 750-gallon pumper truck and crew in San Jose to respond to and provide fire service for the southern Tinian and backup Crash-Fire-Rescue support to West Field. The Navy will request the use of Tinian Fire Department assets for major exercises. The request will be made through the West Field command post. The Navy will maintain airfield crash-fire-rescue equipment and crews at North Field for the duration of the exercise. Any military related fires will be controlled prior to the loss of any wetland or native limestone forest habitat is burned. Any military related fires in tangantangan will be controlled prior to the loss of five acres tangantangan habitat.

V. ROTA

38. No training activities will occur near or within critical habitat, habitat occupied by listed species, or other habitats designed for conservation use. If such activities are planned in the future, the Navy will consult with the USFWS pursuant to section 7 of the ESA. Prior to planning exercises on Rota, MIRC Operations (OPS) will coordinate with appropriate local officials on Rota to determine the latest status of species (e.g., species locations). MITT training will be planned such that ESA species will be avoided in accordance with the "areas to be avoided" map provided by USFWS. In May 2014, USFWS provided a map that represents all areas to be avoided that could be occupied by ESA-listed species at any time

throughout the year. This map was overlaid with proposed training locations, critical habitat, and other conservation areas resulting in MITT Biological Assessment Figure 3-1 (August 2014). Green shaded areas represent all areas that could be occupied by ESA-listed species at any time throughout the year. These areas are not proposed for training.

39. Aircraft overflights on Rota, with the exception of landings and takeoffs as part of training exercises (landings, takeoffs, and insertion events at the Rota International Airport), are prohibited below 1,000 feet (305 meters) AGL and within 1,000 feet of coastlines.

40. Activities that involve aircraft training primarily occur on Guam. Rota will only be used when other locations on Guam or the CNMI are not available, use of these locations is not practical, and/or the training mission requirements cannot be met without the use of Rota.

VI. GUAM

41."No Wildlife Disturbance" and "No Training Areas" are designated on Naval Base Guam Orote Point, Naval Base Guam Munitions Site, and Andersen AFB Tarague Beach. Vegetation removal would be limited to maintaining existing bivouac areas. No new bivouac areas are proposed in the MITT BA. Maneuver units will remain tactical and not establish support camps.

42. All training activities that involve ground maneuvers on Guam will be consistent with the fire management plan included in COMNAVMARIANASINST 3500.4A. DoD will continue to implement the following restrictions at all action areas on Andersen Air Force Base:

a. No vegetation clearing except: maintenance required to keep paved surfaces, landing zones, and the drop zones in a safe and useable condition and for bivouac purposes in the bivouac area. Tree species greater than 4-inches in diameter used for foraging, roosting, or nesting of bats and crows will not be removed.

b. Motorized vehicles shall be driven only on prepared surfaces, in the drop zone and landing zones as required and only rubber-tired vehicles will be allowed; no digging is allowed except in the Northwest Field bivouac area; and no harassment or killing of native wildlife is allowed.

c. Use of pyrotechnics and other incendiary devices is limited to paved surfaces, ground pits, or ceramic-lined rooms.

43. Helicopter overflights as part of training activities are prohibited below 1,000 feet (305 meters) above ground level (AGL) over Northwest Field north of the South Runway. This measure is designed to minimize visual disturbance and acoustic noise impacts on foraging or roosting Mariana fruit bats in the Northwest Field area. The satellite tracking station located at Northwest Field also has a flight restriction of 2,500 feet (760 meters) AGL within 1 nautical mile of the station.

44. Overflights as part of training activities along all Andersen AFB clifflines are prohibited below 1,000 feet (305 meters) AGL.

45. Helicopter overflights as part of training activities are restricted throughout the Naval Base Guam Munitions Site below 500 feet (150 meters) AGL. Fixed-wing aircraft are restricted below 1,000 feet (305 meters) AGL as part of training activities.

46. Riparian wetlands are dispersed throughout the Southern Land Navigation Area and recent surveys have detected moorhens in this area. No maneuver and navigation training will occur in riparian wetlands in this area, in accordance with COMNAVMARIANASINST 3500.4A (Table 3-4, pg. 38 and Fig 3-10, pg. 40).

47. Continuance of amphibious landing standard operating procedures; observation of normal harbor navigation rules, pre-exercise surveys for presence of sea turtles no more than six hours prior to an exercise, directing landing crafts to areas determined to be clear of sea turtles and sea turtle nests, restoration of beach topography using hand tools after exercises, monitoring of landing sites during night-time landing activities). These include:

a. The Navy implements restrictions on landings and launches at beach and boat ramp locations to minimize impacts to sea turtles and their habitats.

b. The Navy maintains restrictions on landings and launches, such as the use of the concrete boat ramp at Sumay Cove, which is across from potential sea turtle nesting habitat.

c. The Navy implements speed restrictions to avoid creating wakes; the use of the Sumay Cove ramp avoids and minimizes effects to sea turtle nesting sites.

d. Currently, training does not occur on other Guam beaches that support sea turtles. Should the Navy decide to use other Guam beaches for amphibious landings, the Navy will implement appropriate measures.

48. The USAF implements training and operation restrictions at the Combat Arms Training and Marksmanship (CATM) range adjacent to Tarague Beach, Andersen AFB to minimize effects to sea turtles and Mariana fruit bat.

a. Night-training occurs at the CATM range; therefore night-lighting is installed. The lighting configuration at this location is maintained with four flood lights, located below the tree canopy level that are directed inland and parallel to the coast. Lighting in this configuration will avoid impacts to nesting and hatching sea turtles and Mariana fruit bats.

b. The CATM range allows for training with small arms, inert mortars to 60 millimeter, and 40 millimeter grenade launchers. These weapons do not produce percussive force and no weapons that produce percussive force can be used at this facility.

Rear Admiral Bette Bolivar
Department of the Navy
Joint Region Marianas
Building 200, Room 326
Halsey Drive, Nimitz Hill
Piti, Guam 96915

Subject: Revision to Biological Opinion on the Mariana Islands Training and Testing Program

Dear Admiral Bolivar:

This follows up on our letter of April 14, 2015, regarding a term and condition in our February 20, 2015 biological opinion on the Mariana Islands Training and Testing (MITT) Program. We are enclosing an amendment to the biological opinion that revises the term and condition.

As originally written, the term and condition called for the Defense Department (DoD) action agencies to eradicate introduced ungulates on the island of Aguiguan in order to minimize the effects of habitat destruction causing take of the endangered Micronesian megapode. After further discussion between DoD and the Fish and Wildlife Service (Service), we have prepared a revision to provide flexibility in how the intended result is achieved and address DoD's concerns regarding implementation. Under the term and condition as revised, DoD will provide funding, not to exceed $1.77 million, for invasive vertebrate pest control and the Service will implement the control action. As part of implementation, the Service will identify where control will be conducted, comply with all applicable legal requirements, and provide DoD with an implementation plan and budget. The term and condition also states that, except for the funding, DoD is not responsible for project implementation or results, and failure to implement or achieve the desired results will not be cause for reinitiation.

If you have any questions regarding this Biological Opinion, please contact Earl Campbell at the letterhead address or by telephone at (808) 792-9400.

Sincerely,

for Mary M. Abrams, PhD
Field Supervisor

cc: Richard Seman, Secretary, CNMI Department of Land and Natural Resources

COPY

ADDENDUM TO BIOLOGICAL OPINION ON THE MARIANA ISLANDS TRAINING AND TESTING (MITT) PROGRAM

The biological opinion for the MITT program, dated February 20, 2015, is hereby revised by deleting paragraph 1.1 of the Terms and Conditions and replacing it with the following.

1.1 The DoD action agencies for the MITT program shall provide funding, not to exceed $1.77 million, for invasive vertebrate pest control to be implemented by the Service to minimize the effect of take on the Micronesian megapode. The Service will be responsible for identifying where invasive vertebrate pest control will be conducted; complying with all applicable legal requirements and obtaining required approvals; providing DoD with an implementation plan and associated budget; implementing the control action; and responding to related media inquiries. Except for providing the necessary funding, DoD is not responsible for project implementation or the results thereof, and failure to implement the control project or achieve the desired results will not be cause for reinitiation.

JUL 2 6 2016

Colonel Douglas Waddingham
Chief of Operations
94th Army Air and Missile Defense Command
Joint Base Pearl Harbor-Hickam, Hawaii 96818

Subject: Biological Opinion for Permanent Stationing of the Terminal High-Altitude Area Defense System on Andersen Air Force Base, Guam

Dear Colonel Waddingham:

This document transmits the U.S. Fish and Wildlife Service's (Service) biological opinion based on our review of the emergency placement and permanent stationing of the Terminal High-Altitude Area Defense System (THAAD), on Northwest Field, Andersen Air Force Base (AAFB), in northern Guam and its effects on the endangered Mariana crow (*Corvus kubaryi*) (crow), Guam rail (*Gallirallus owstoni*) (rail), Guam Micronesian kingfisher (*Todiramphus cinnamominus cinnamominus*) (kingfisher), the threatened Mariana fruit bat (*Pteropus mariannus mariannus*) (fruit bat), *Cycas micronesica* (cycad), and *Tabernaemontana rotensis*. Your request for formal consultation was received on February 9, 2016. Our response is in accordance with section 7 of the Endangered Species Act (Act) of 1973, as amended (16 U.S.C. 1531 *et seq.*). This biological opinion is based on information provided in your letter and biological assessment, discussions between the Service and the Army, and other information in our files. A complete administrative record of this consultation is on file at the Pacific Island Fish and Wildlife Office (PIFWO).

In addition, pursuant to the requirements identified in the Cooperative Agreement between the U.S. Air Force, Department of Navy (DON), and the Service for the establishment and management of the Guam National Wildlife Refuge, we have provided coordination regarding potential impacts to the Guam National Wildlife Refuge Overlay from the proposed project. This consultation reviews anticipated effects to the listed species and federally designated critical habitat in Guam. In this consultation, habitat is defined as the habitat that is currently suitable to support the survival and recovery of listed species.

Consultation History

March 12, 2013: JRM informs the Service of the emergency deployment of the THAAD.

August 7, 2013: JRM staff spoke with Service staff via phone and email about the necessity of a new consultation because the JGPO 2010 and Cargo Drop Zone (CDZ) (2001-F-0001) could

potentially cover the habitat modification and effects of the THAAD action. However, the Navy may decide to pursue a new and separate consultation.

August 27, 2013: Service staff informs Joint Region Marianas (JRM) staff that the THAAD missile defense system cleared area could be covered under the 2010 JGPO BO (2010-F-0122) and requested total acreage to confirm if the JGPO BO, combined with the Cargo Drop Zone BO would cover the extent of the THAAD clearing.

On May 16, 2013, Mark Cruz and Anne Brooke from JRM contacted Earl Campbell, Loyal Mehrhoff, and Leilani Takano of the Service by phone to discuss the consultation process for the THAAD missile battery that was deployed on an emergency basis in April 2013.

On May 30, 2013, Anne Brooke from JRM, and Leilani Takano and Ann Marie Gawel of the the Service, visited the THAAD site.

During August 2013, Anne Brooke (JRM) and Leilani Takano (Service) exchanged emails to clarify the consultation process and relation of expeditionary deployment of the THAAD battery to other completed and ongoing consultations for Department of Defense (DoD) activities on Guam.

During February 2014, Anne Brooke (JRM) and Leilani Takano (Service) exchanged emails regarding the status of the emergency consultation for the expeditionary deployment of the THAAD battery.

March 14, 2014: JRM email to Service staff informing the Service that JRM will be preparing a BA for THAAD.

In September 2014, the Air Force submitted a BA that describes the effects of modifying the CDZ training area on listed and proposed species (AAFB 2014) and requested re-initiation of consultation on September 25, 2014.

On September 10, 2014, representatives of the U.S. Army Space and Missile Defense Command on behalf of the 94th Army Air and Missile Defense Command (AAMDC), and their contractor HDR, met at Guam National Wildlife Refuge with Ecological Services and Refuge staff to discuss the expeditionary deployment of the THAAD battery, describe plans for permanent stationing and operation of the battery, and discuss plans for consultation on this project.

The Service responded on October 30, 2014, and concurred that the proposed modifications were not likely to adversely affect the Guam rail or Mariana fruit bat. However, the Service could not concur that the action was not likely to adversely affect the Mariana crow and Guam Micronesian kingfisher, and therefore requested additional information in order to complete a formal consultation (a Biological opinion) on these species.

On February 18, 2015, representatives of the 94th AAMDC and U.S. Army Space and Missile Defense Command met with Stephen Miller, of the Service, in Honolulu, Hawaii, to discuss the

content of this BA, and the plans of the 94th AAMDC to complete the consultation process for this emergency circumstance.

On March 18, 2015, the Service received a request from DON JRM to discontinue the reinitiation of consultation for Parachute Cargo Drop Training.

On March 26, 2015, the 94th AAMDC submitted a BA and request for concurrence that the emergency deployment and expeditionary operation of the THAAD missile battery in Guam may have affected, but was not likely to have adversely affected the Mariana fruit bat.

The Service responded on September 15, 2015 (letter from K. Young, Service, to Major D. Simmons, 94th AAMDC) stating that they have concluded that actions associated with the deployment and stationing of the THAAD missile battery may affect, and are likely to adversely affect the Mariana fruit bat, Mariana crow, Guam Micronesian kingfisher, and Guam rail, and that formal consultation is therefore required for this project.

On October 8, 2015, representatives of the 94th AAMDC and the Service held a teleconference to discuss the Service's September 15 letter, the future consultation process, and suggested conservation measures.

On 12 October, 2015, Service staff sent the 94th AAMDC revised data layers for habitat of the fruit bat, kingfisher, crow, and rail.

On February 9, 2016, the Service received a request from the 94th AAMDC for consultation on this action.

On February 29, 2016, the Service sent a letter indicating all information required to initiate formal consultation was provided or otherwise accessible for consideration and reference.

On March 18, 2016, Service staff met with representatives for 94th AAMDC via teleconference to discuss further clarifications and to touch base on status of the BO.

PROJECT DESCRIPTION

This action consists of the placement of the THAAD missile battery, which occurred through an emergency action, in April 2013. This consultation covers that emergency action, as well as proposed activities linked to it: a shift (compressed) placement of the THAAD facility, supporting infrastructure, as well as the proposed relocation of Parachute Cargo Drop Zone (CDZ) activities to an adjacent runway. The activities included in the CDZ were analysed in a previous biological opinion (2001-F-0001). The new clearing necessary to carry out these activities are analysed below, in conjunction with the THAAD placement and operation. Since no end date or project length can be anticipated at this time, the proposed action and resulting effects are considered to continue indefinitely in this analysis.
In April 2013, a THAAD missile battery was deployed to Guam on an emergency basis in response to potential hostile North Korean missile launch activity. Currently, the THAAD battery is still in place at Andersen AFB and operating as an expeditionary (temporary) mission.

The THAAD battery (including support facilities, radar, and launch platforms) was placed in an area surrounding the eastern end of the North and South Runways of Northwest Field (NWF) (Figure 1).

During the initial deployment of the expeditionary THAAD missile battery in April 2013, a 249.4-acre emplacement was occupied by Task Force Talon, including a 12.0-acre motor pool established south of the original expeditionary emplacement. Temporary fencing was placed around the site and temporary wooden guard towers were erected within cleared areas.

About 68.3 acres (28 percent) of the 249.4-acre original expeditionary emplacement was comprised of paved runways, taxiways, ramps, and other hard surfaces prior to the expeditionary emplacement. Approximately 145.4 acres (58 percent) of the emplacement, primarily between, and to the east of the runways, were maintained as low, mixed herbaceous scrub for safe operation and use for training activities. The remaining 35.7 acres (14 percent) were forest, scrub, and herbaceous cover. During site preparation for the expeditionary deployment of the THAAD missile battery, all trees and other vegetation on the remaining 35.7 acres were removed and piled within the project site. Estimates of vegetative cover are based on a survey of vegetation on Andersen AFB completed in 2007 (e2M 2008).

Based on habitat maps provided by the USFWS in 2015, 28 to 30 acres of the area cleared in April 2013 was habitat for the Mariana fruit bat, Guam Micronesian kingfisher, and Mariana crow, and 138 acres was habitat for the Guam rail.

• *Fire Control and Communication*: This system component exercises direct control and management of the missile battery, providing the human interface of the automated system functions.

• *Radar Unit*: The radar provides a broad range of surveillance services that perform target search, acquisition, identification, and tracking functions.

• *Interceptor*: The interceptor missile intercepts an incoming hostile missile threat.

• *Launch Platform/Fire Unit*: The truck mounted launchers transport, aim, and launch the interceptor missiles. The THAAD launcher carries a missile round pallet that contains up to eight missiles.

The 12.0-acre motor pool area was established for equipment maintenance and storage, on existing pavement south of Area 50 (which was established and fenced in 1991) (Figure 1). Within the motor pool, one office container (8 feet x 40 feet), one portable Airbeam shelter (40 feet by 56 feet), and other storage containers were installed.

Within the cleared emplacement area, additional changes were made in 2014 for improved system operations during the expeditionary mission. These changes have included compressing the THAAD emplacement perimeter into an 82.0-acre area to allow for greater operational flexibility (Figure 2). The boundary of this compressed expeditionary emplacement falls within the original expeditionary emplacement. Within the new fence line, additional temporary wooden guard towers have been erected.

To provide a more stable foundation for the primary THAAD equipment, several individual concrete pads have been added for the launchers and radar placement, for a total pad area of approximately 28,200 square feet. Additional grading within the compressed expeditionary emplacement was required prior to constructing some of these pads, but no additional vegetation clearing was required. No other clearing or construction is planned for the current expeditionary mission.

Existing billeting and support buildings within the Andersen AFB cantonment area have been repurposed to support the THAAD battery and mission-related personnel. The old base post office, for example, serves as headquarters for Task Force Talon and existing billeting (Tinian Hall) provides housing for the task force's soldiers. Additionally, for munitions storage, the THAAD mission is using existing bunkers located in the Munitions Storage Area 1 just south of the motor pool.

Current expeditionary operations consist of continuous radar surveillance, facility security, routine facility and equipment maintenance, and battle drills (i.e., computer simulations that do not include missiles being launched). Approximately 190 military and 10 civilian support personnel are deployed in support of the THAAD mission. Those personnel are housed in military transient quarters on Andersen AFB and deployed on a rotational, temporary duty assignment basis. Operations are in shifts, which include a mix of approximately 60 contract personnel, military police, and soldiers per shift. Government vehicles are used to travel to and from the battery site.

An X-band radar system has been operating and is proposed to continue operating as a part of this action. The radar system emits electromagnetic radiation (EMR) that could cause tissue damage to wildlife. Radar units normally operate in search/surveillance mode, except when tracking a target or being calibrated or tested. In search/surveillance mode, the main beam of the radar is not aimed at any area in space for more than a small fraction of a second, and the search beam moves in a random pattern. However, during tracking or calibration mode, the beam is steady. Calibration is performed on start-up and on regular intervals, issues, and tracking mode occurs when the unit is actively tracking a flying target such as a missile or a plane. In this mode, the main beam will move in an angle to keep the target in the center of the beam. Targets are normally hundreds of kilometres away. Therefore, while the moving beam might be tracking a fast-moving target, it will be moving slowly at close proximity to the unit – linear velocity of less than 2.5 meter/second (5.6 miles per hour) at 350 meters from the radar (Moran 2015, p. 3)

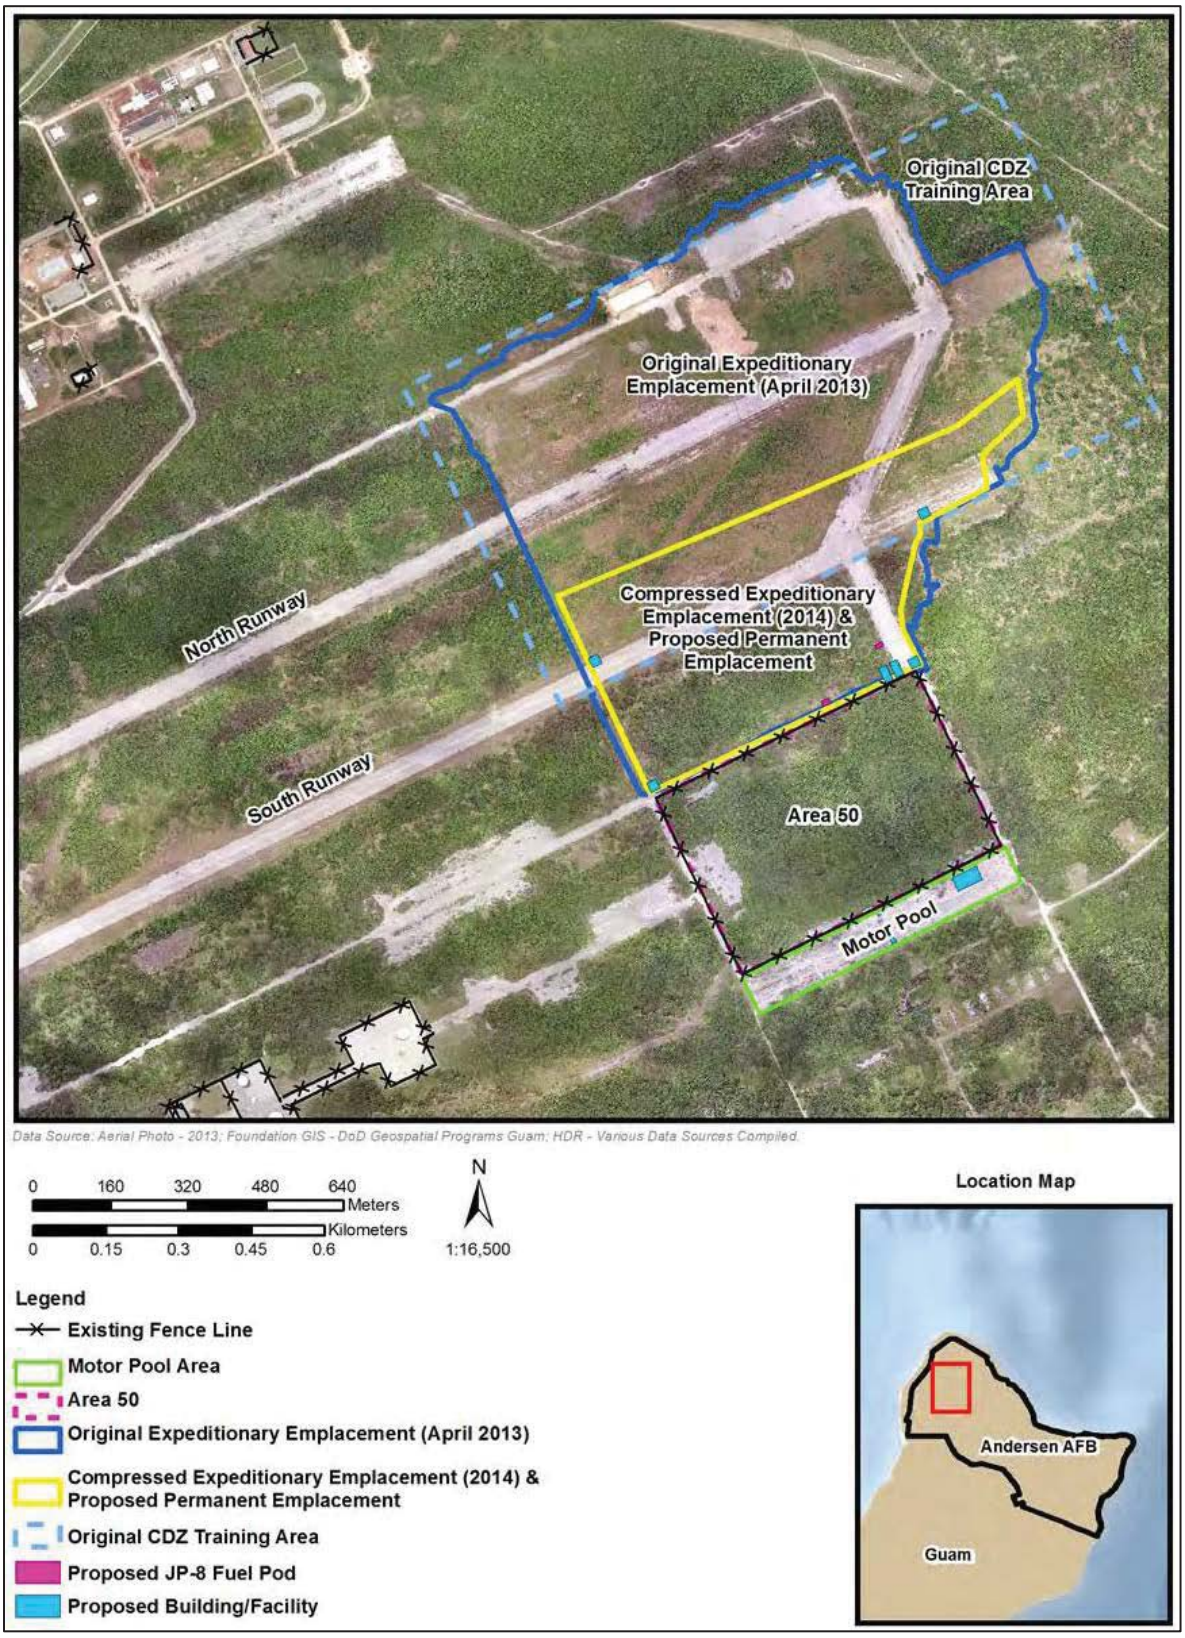

Figure 1. Original THAAD emplacement (figure taken from 2016 BA).

For the permanent stationing of the THAAD battery at NWF, all facilities would be located within the compressed expeditionary emplacement and motor pool footprints shown in Figure 2. All project facilities and activities, with the exception of a fiber-optic communication line

(described below), would be located on existing paved surfaces or within areas maintained or previously cleared of vegetation.

The following facility and site improvements would be installed or developed to meet operational requirements (e.g., power, communications, shelter, and motor pool support) and security protection requirements (e.g., fencing, lighting, and entry control and monitoring systems).

Two security fences would be installed along the perimeter of the proposed permanent emplacement. Each fence would be approximately 7 feet tall and spaced approximately 30 feet apart. Intrusion detection systems would be installed along the fence line. Lighting systems that are shielded and facing downward would also be placed along the fence perimeter. Electrical power and cabling along the new fence line would be trenched underground or encased in hardened conduit.

• *Motor Pool Fence*: The motor pool and roadway along the eastern side of Area 50 would be secured by a single, 7-foot-tall chain-link fence. This new single fence would connect to the existing Area 50 fence and to the dual perimeter fence securing the emplacement site.

• *Concrete Guard Towers*: The current temporary guard towers within the proposed permanent emplacement site would be replaced with four concrete guard towers measuring approximately 20–25 feet in height.

• *Entry Control Facility*: As part of the perimeter security system, an entry control facility building would be constructed at the western end of the motor pool to control entry to authorized personnel and vehicles. The one story building would be approximately 160 square feet.

• *Power Generators*: For improved power generation efficiency at the THAAD battery site, most of the system tactical generators would be replaced with fewer portable generators ranging from 420 kW to 1.3 MW, which would power the emplacement site at all times. To improve fuel storage requirements for the generators, two 10,000-gallon (37,854-liter) JP-8 above-ground fuel pods would be placed nearby. Each pod would be double walled with built-in spill sensors. Delivery and use of power from island electrical circuits is not contemplated at this time, but replacement of generator power with island commercial power could occur in the future.

• *Utilities*: A 2.9-mile fiber optic communications line would be trenched from the Rapid Engineer Deployable Heavy Operational Repair Squadron, Engineer installation on NWF to the emplacement site and to other facilities just to the west (Figure 3). The communication line would be located along existing roadways, paved surfaces, or other disturbances wherever possible. About 5.4 acres would be disturbed, 2.5 acres of which is developed land and 2.9 acres is vegetated with forest or scrub.

• *Big Voice System*: The installation of a big voice system would give the THAAD battery a means to warn personnel of an incoming missile attack or weather advisories. The system would include speakers mounted on a single pole and it would be tied to the phone system to announce warnings at the THAAD emplacement site. The system would be audible out to about 6,560 feet.

• *Roadways*: Within the compressed emplacement site, additional roadway segments would be graded for adequate vehicular access along the fence line. Additionally, pavement improvements to existing roadways leading to the site may be needed. All roadway improvements would be within the compressed expeditionary emplacement or within previously paved areas.

• *Fire Direction Center:* As part of permanent stationing, a fire direction center building for the THAAD battery would be constructed at the southern end of the current emplacement site for operations and administrative support. The single-story, reinforced concrete building would measure 20 feet by 50 feet.

• *Communication Trough*: Between the THAAD radar and the fire direction center, a communication trough would be excavated to run cables. The trough would measure up to 4 feet deep and be constructed of concrete.

• *Drainage System*: To channel storm water away from THAAD equipment at the southern end of the emplacement site, a drainage culvert would be excavated and lined with concrete to funnel water to a ravine at the eastern side of the site. The drainage system also would include installation of an asphalt pad to redirect storm water towards the culvert.

• *Security Control Center (SCC)*: A new building for the security control center also would be constructed at the southern end of the current emplacement site for security force use. The single-story, reinforced concrete building would measure 20 feet by 50 feet.

• *Tactical Equipment Maintenance Facility*: Within the next 3 to 5 years, the current AirBeam shelter in the motor pool area would be replaced with a permanent reinforced concrete, open bay warehouse building of larger size (measuring approximately 70 feet by 107 feet in area. The new facility would be used to provide space and equipment storage for maintaining THAAD mission-related vehicles and associated equipment for all levels of maintenance below depot level. Typical operations in the facility would include inspection, lubrication, preventive maintenance, diagnostic analysis, welding, and replacement of major components.

Once the new facilities are installed and other site improvements completed, day-to-day operations, training, and maintenance activities for the THAAD battery are expected to be similar to that of the expeditionary mission described above. Total THAAD personnel numbers would increase slightly, to approximately 225 of mostly military personnel. In addition, approximately 70 families (about 168 dependents) would move to Guam and be placed in existing or future JRM housing on the island (depending on availability of installation housing). Required support facilities for military personnel and their dependents would be provided through the JRM installations on Guam. No additional facilities, beyond the facilities within the JRM quality of life support structure have been identified.

Exclusion zones established to avoid injury and damage to personnel and equipment from EMR emitted from the THAAD system radar will be maintained, and a permanent airspace restriction will be developed pursuant to FAA regulations.

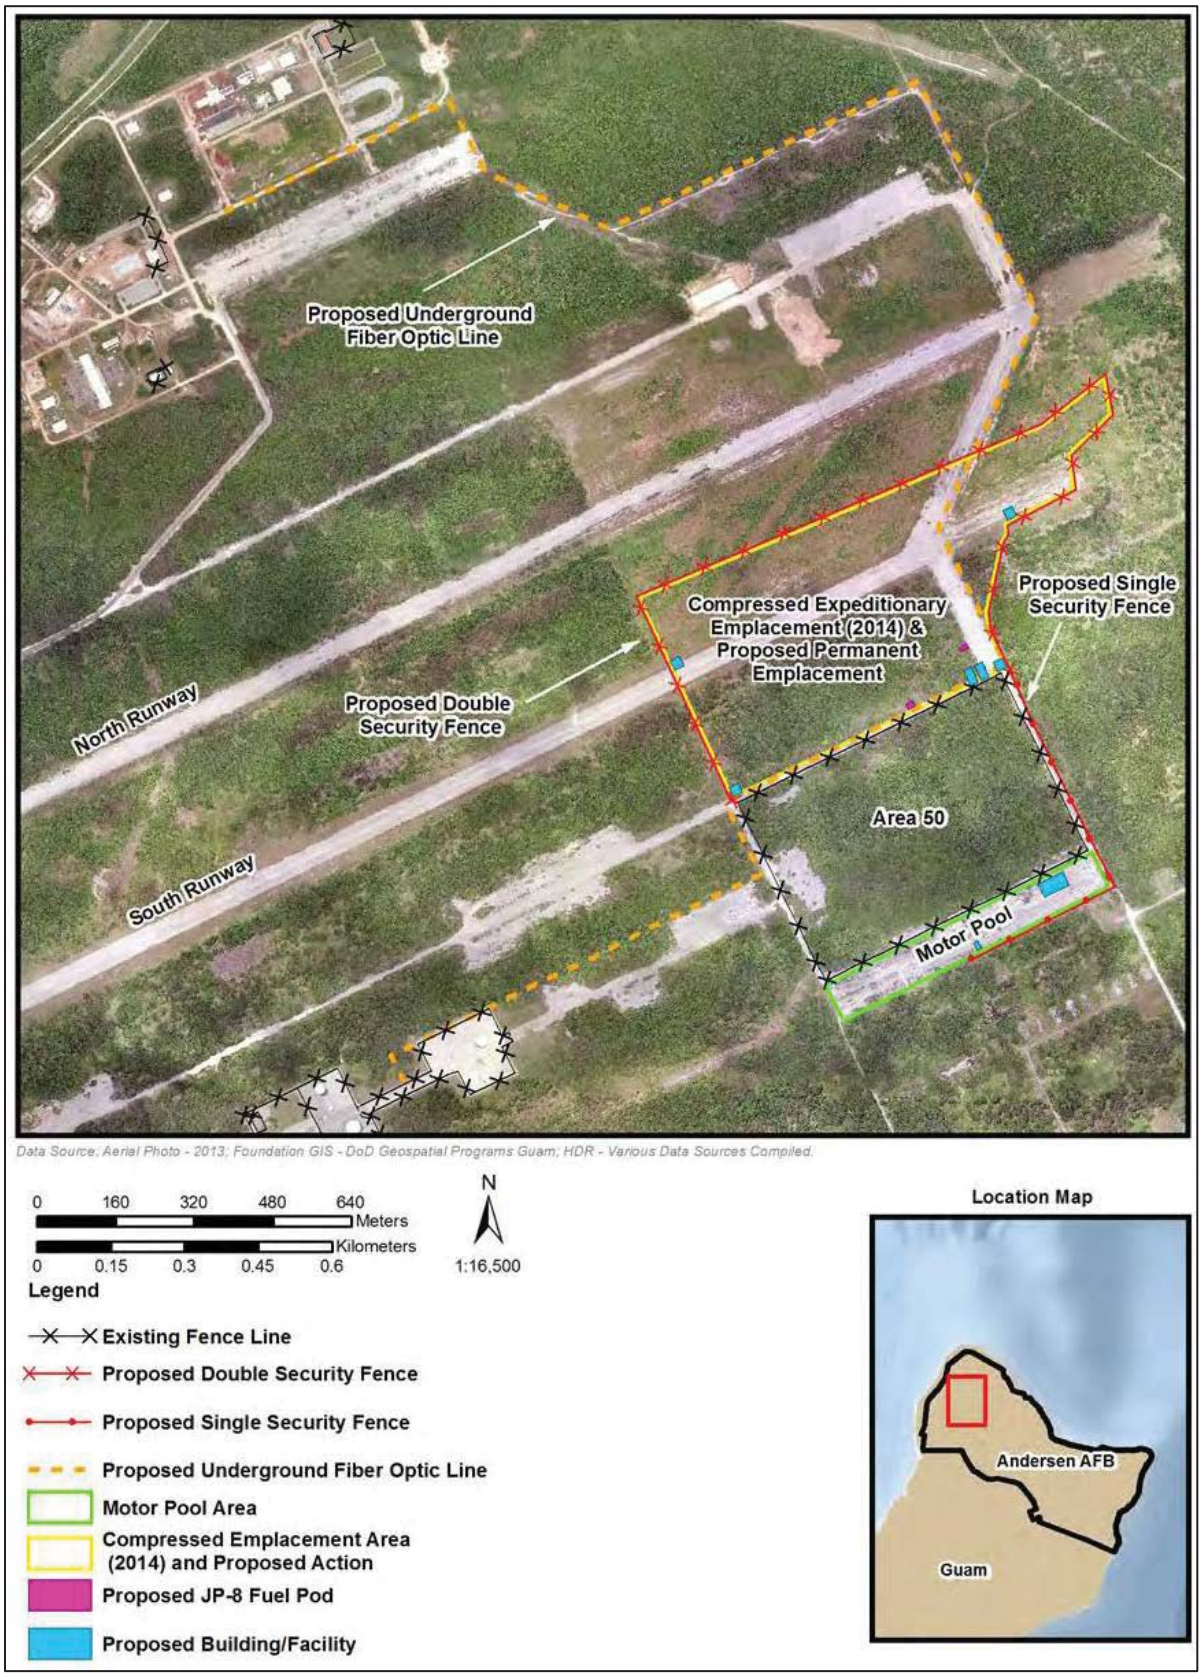

Figure 2. Permanent emplacement (taken from BA, 94th AAMDC 2016).

The new NWF CDZ training area will be approximately 1,950 by 4,500 feet (201.5-acres) (Figure 3) and will be located at the eastern end of the North Runway. To prepare that area, a

288-foot-wide, 29.7-acre area along the northern edge, and outside of, the original 248-acre NWF CDZ must be clear of vegetation. About 3.0 acres there were cleared for the THAAD expeditionary emplacement, leaving 26.7 acres remaining to be cleared. In addition, vegetation might be removed from some areas within the original NWF CDZ training area that remain partially forested, including within a 22.4-acre tract in the north eastern corner of that area. Vegetation might also need to be removed from other, smaller areas within the original training area. Clearing of vegetation within the original NWF CDZ, including the 22.4-acre tract and other small areas that might be cleared, was addressed in the 2000 CDZ biological opinion (USFWS 2000), and loss of habitat and other effects on the species listed at that time, are considered as part of the baseline for analysis of effects of the projects addressed in this BA. To comply with the United States Air Force's runway design specifications for C-130 and C-17 aircraft assault landing zone exercises, all vegetation along the north shoulder (19.0 acres), south shoulder (18.9 acres), and west glide slope area (14.0 acres) of the North Runway, will also be cleared of vegetation using heavy equipment (Figure 3). These areas, totalling 51.9 acres, are outside of the original NWF CDZ, and were not considered in the 2000 CDZ biological opinion.

The south western and south eastern corners of the original CDZ have not been cleared of vegetation, and will now be outside of the CDZ training areas (Figure 3). There are no plans to disturb these two forested areas, which total 15.9 acres, for either the CDZ modification or permanent stationing of the THAAD battery.

All areas to be cleared would be grubbed and graded, and the trees and other vegetative debris piled around the cleared perimeters. It is estimated that it will take about 3 months to complete the vegetation removal.

In summary, a total of 81.5 acres located outside of the original 248-acre NWF CDZ evaluated in the CDZ biological opinion (USFWS 2000) would be cleared, about 70.2 acres of which is forested or covered with perennial shrubs; the remainder is developed land or covered with herbaceous scrub.

In addition to vegetation clearing, resurfacing of the existing North Runway would occur as part of the reconfigured CDZ site. All such improvements would be conducted within previously paved areas. The airborne training activities and exercises at NWF are analysed in the CDZ biological opinion (USFWS 2000).

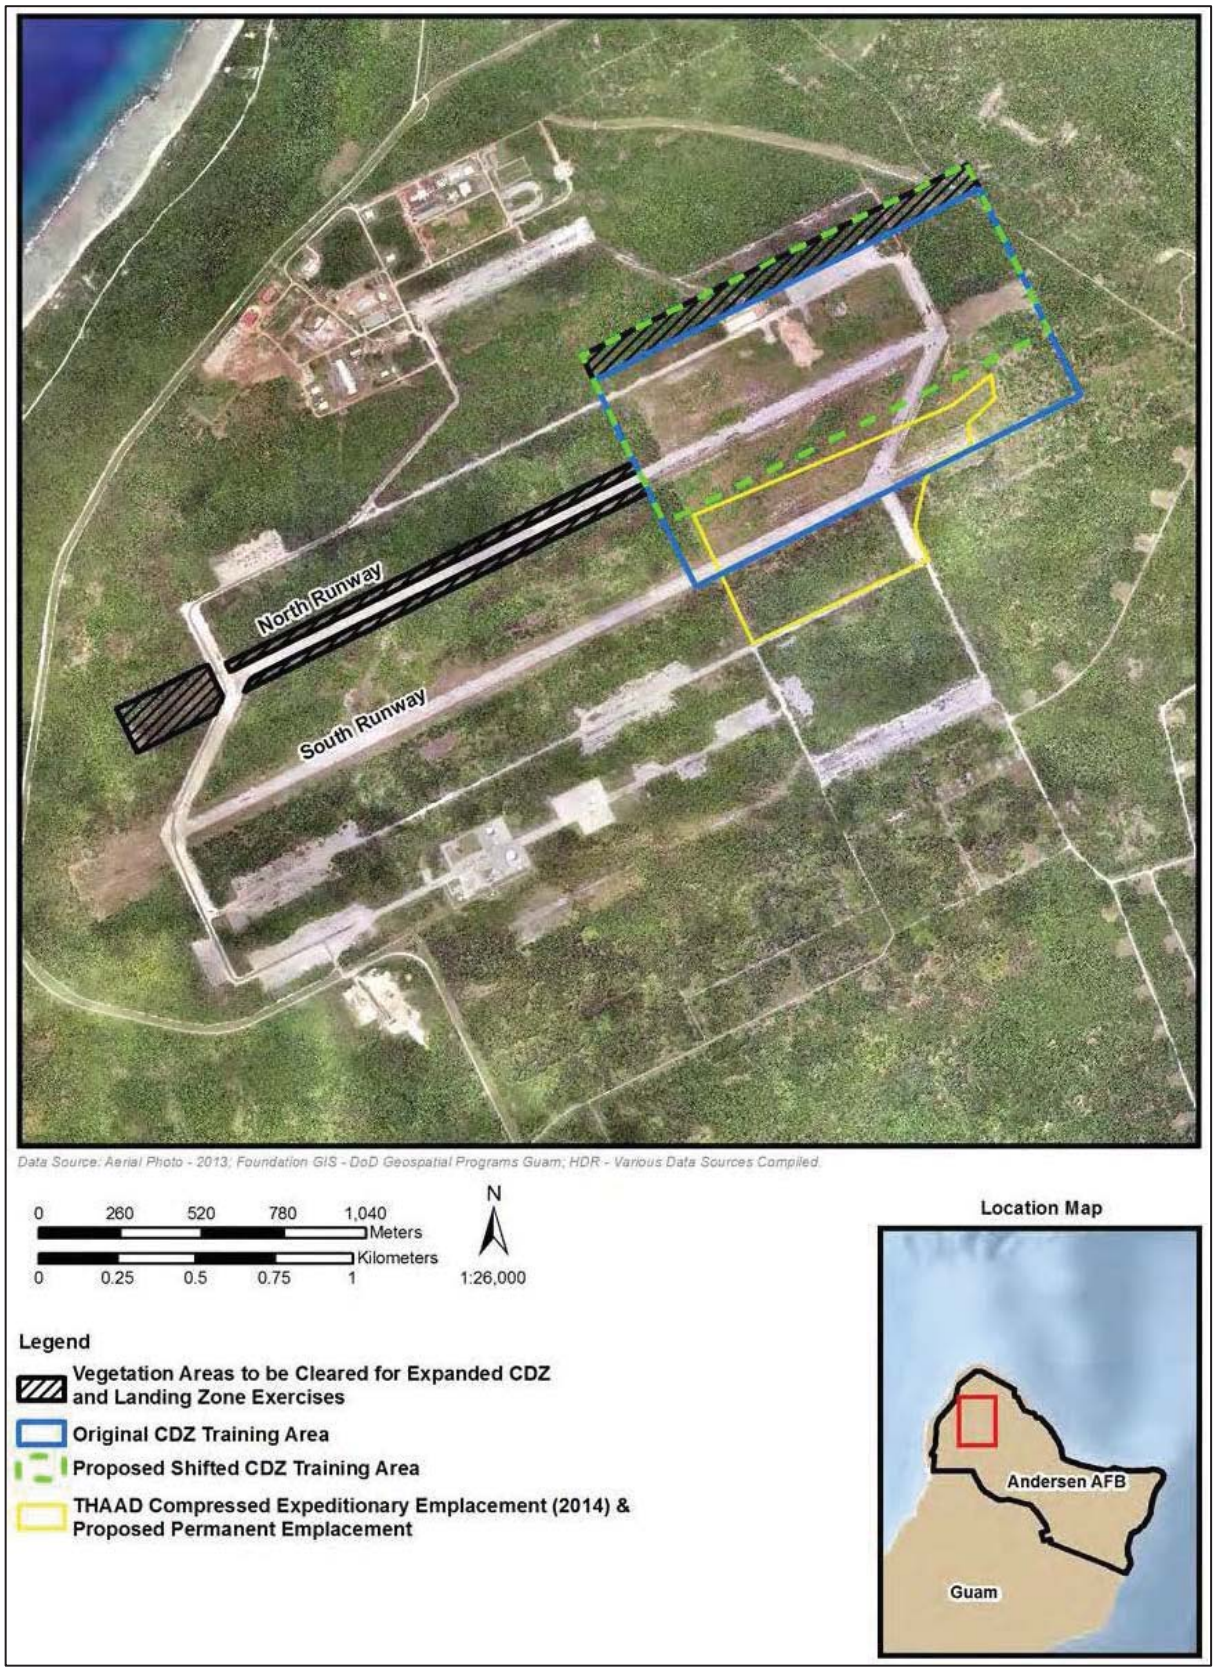

Figure 3. Cargo Drop Zone areas to be cleared (taken from BA, Army 2016).

Description of the action area

The action area consists of mixed limestone forest plateau (secondary), *Casuarina* forest, *Hibiscus* scrub, *Eugenia* forest, *Vitex* forest, mixed herbaceous scrub, and developed land (Figure 4) (e^2M 2008). The finished and proposed activities in this action are within or adjacent to the Northwest Field runways, which were constructed towards the end of World War II in 1944-1945. Much of the vegetation that has grown back over the past 70 years adjacent to these runways remains scrubby and disturbed, dominated by *Casuarina equisetifolia* (ironwood), a native tree characteristic of secondary growth and forest edges. However, many forest species characteristic of primary and secondary limestone forest are interspersed such as *Ochrosia oppositifolia*, *Algaia mariannensis*, and *Guamia mariannae* (A. Gawel, Service, pers. observations 2012-2015). Many invasive plant species also persist within the project footprint, such as *Lantana camara*, *Vitex parviflora*, and *Triphasia trifolia* (A. Gawel, Service, pers. observations 2012-2015).

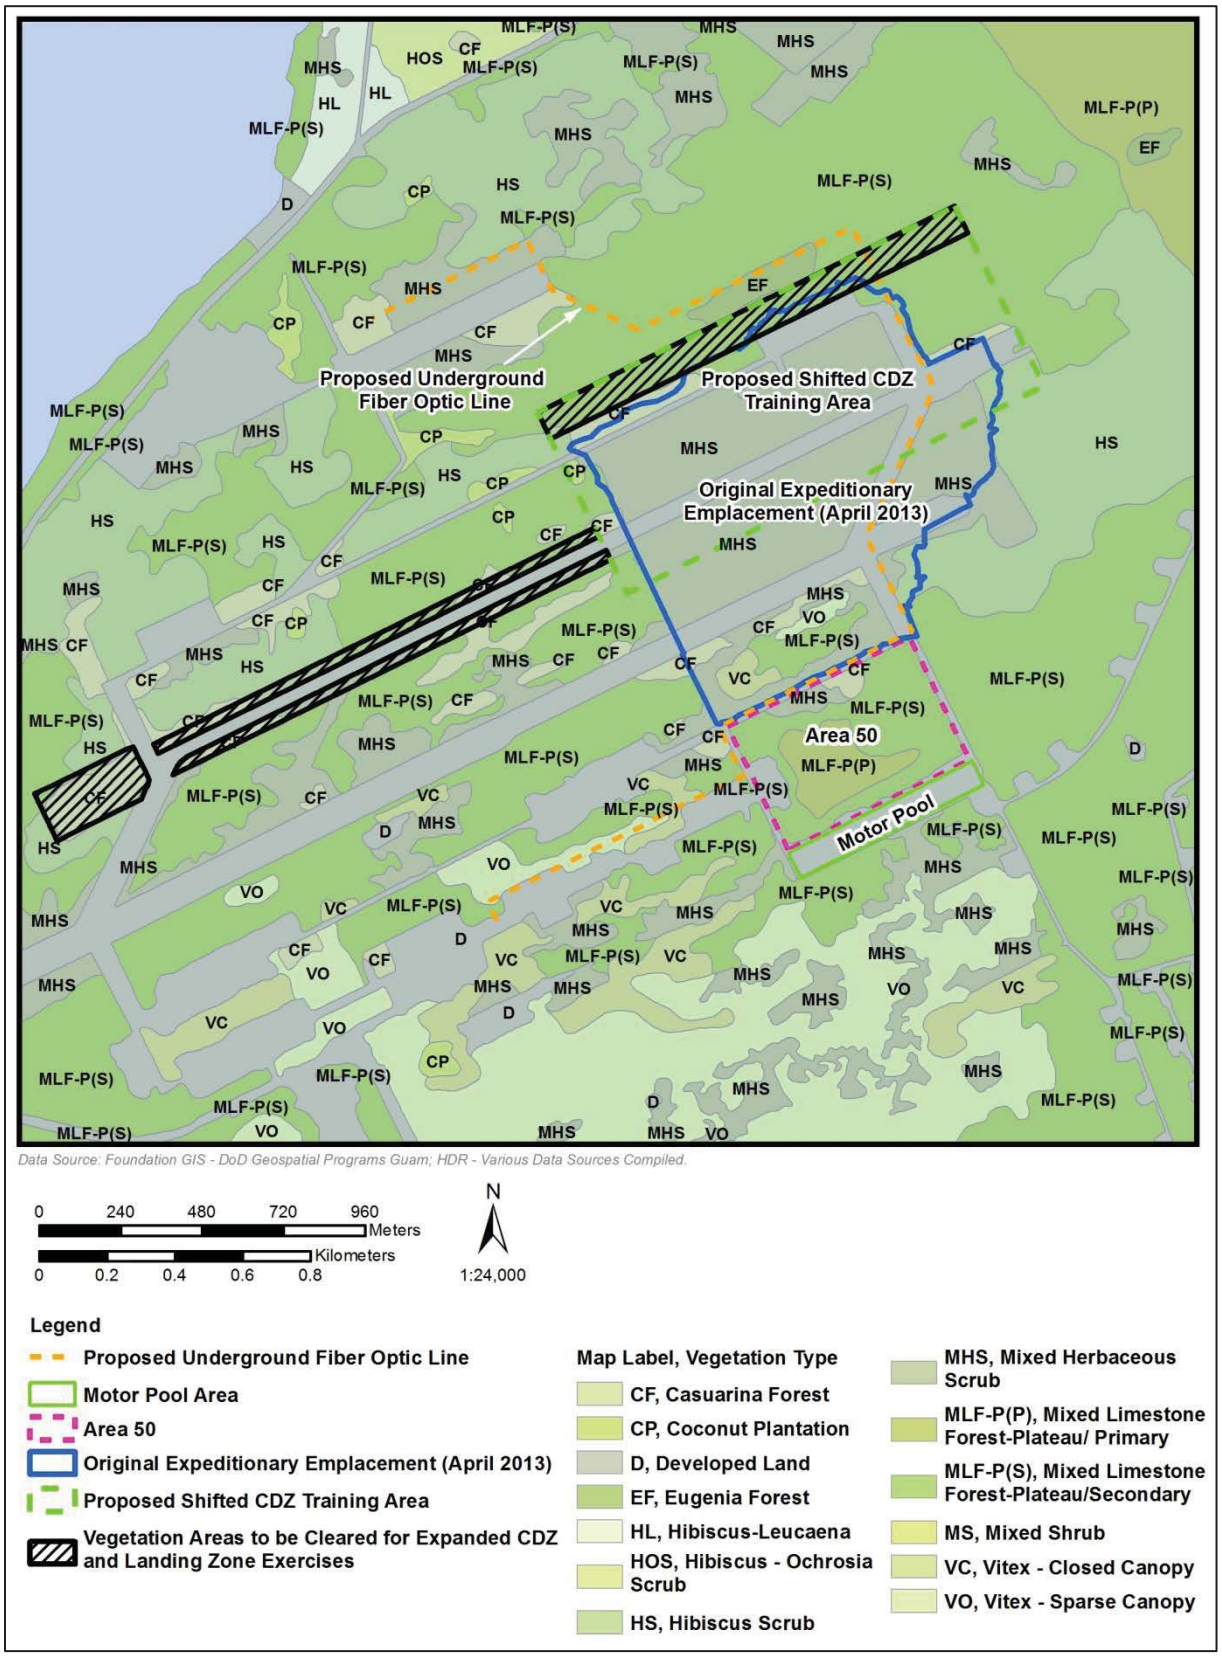

Figure 4. Vegetation communities within and around project footprint. (taken from BA, 94th AAMDC 2016).

Conservation, Avoidance, and Minimization Measures

The following measures to minimize and avoid effects of proposed activities; prevent or reduce the spread of invasive species; and compensate for the loss of habitat currently used by threatened and endangered species on Guam, and that could be used by extirpated species when reintroduced onto Guam, will be implemented by the U.S. Army for the emergency and permanent stationing of the THAAD missile battery on NWF and for modification of the CDZ training area. As the lead agency requesting consultation, the U.S. Army, 9^{4th} Army Air and Missile Defense Command (AAMDC) (94th AAMDC 2016, p. 1-1) will ensure that these measures are carried out. They are a part of the project description.

Avoidance and Minimization for fruit bats: All vegetation clearing and construction activities will occur during daylight hours in order to minimize disturbance to bats. One week prior to vegetation clearing and construction, a qualified biologist will survey the proposed project areas at night and during the day to determine of fruit bats are present. If fruit bats are observed in the project area, clearing and construction will be postponed until the fruit bats have left the area out of their own volition.

Fiber Optics Line Preconstruction Survey: Prior to installation of the fiber optics line, a survey would be conducted of the proposed route for listed species. If any individuals of those species are found, the route will be modified to the maximum extent possible to avoid harming, or otherwise adversely affecting, individuals of those species. Viable saplings and other small individuals of these species, that cannot be avoided, will be collected and transplanted to undisturbed areas.

CDZ Surveys and Plant Relocation: Before additional forested areas are cleared to relocate the CDZ and expand the glide slope and shoulders of the North Runway, a survey would be conducted to locate *Cycas micronesica, Tabernaemontana rotensis,* and any other listed plants. Transport all individuals of listed species, unless the advanced maturity of the plant and other biological circumstances would negate the safe transplant of that specimen, to protected areas.

Lighting: All security lighting on the perimeter fence, at the entry control facility, and elsewhere, will be shielded and pointed down to reduce lighting of surrounding forested areas.

Brown Treesnake Interdiction: THAAD, as a tenant Command located on AAFB within JRM, will continue to comply with 36 Wing Instruction 32-7004 Brown Treesnake Management and additional measures that may be developed by JRM in the future, and when applicable will participate in compliance with the *Regional Biosecurity Plan for Micronesia and Hawaii* (DON 2015). The equipment and materials to be shipped by the Task Force is a very small portion of the materials shipped through DoD and commercial ports on Guam; therefore, ongoing operations and permanent stationing of the THAAD missile battery should not stress the capacity to interdict brown treesnakes there.

Protection and Enhancement of Habitat: The 94th AAMDC, Andersen AFB, and JRM will establish two conservation areas on Andersen AFB totalling 334.7 acres to compensate for the loss of habitat of listed species Figure 5. One conservation area of 330.1 acres would be established south and east of the Andersen AFB main base. The site is contiguous with undisturbed land south of the installation that is owned by the Government of Guam. A second, 4.6-acre site would be conserved in an area northwest of the main base. This second site is

contiguous with a much larger conservation area that is being set aside for durable habitat protection as required by the BO for the JGPO Guam Military Relocation (USFWS 2015a), and as specified in the June 2015 *Memorandum of Agreement (MOA) between the Department of Navy and U.S. Fish and Wildlife Service Regarding Conservation of Guam, Micronesian Kingfisher Recovery Habitat in Northern Guam*.

The new conservation areas will be established and managed to support the following: 1) brown treesnake (BTS) control and suppression to facilitate the larger goal of suppressing snake population levels that will ultimately support kingfisher survival and recovery; 2) support for BTS control and eradication methods development, focusing on tools and techniques needed for landscape level survival and recovery of the kingfisher, 3) ungulate fencing and eradication; 4) control of small mammalian predators; 5) invasive plant control and eradication; 6) native plant restoration; and, 7) localized control of introduced invertebrates that may negatively impact kingfisher nesting/fledging. The Army will commit funding conservation actions within these 334.7 acres above execution year INRMP funding levels (as adjusted for inflation) for the next ten years, subject to Congressional authorization and appropriation. This additional funding will be used to support projects that fall within one of the seven focal activities identified

The conservation areas will total about 334.7 acres. The final size and shape of the established areas might differ from those shown in Figure 5, especially if and when a boundary fence is installed, as that fence will need to avoid steep topography and other obstacles. However, the areas will be designed to conserve approximately 3.9 acres for every acre of Guam Micronesian kingfisher habitat that has been or will be disturbed for the activities addressed in this BA, based on the September 15, 2015 letter from USFWS to the 94th AAMDC. A total of 85.8 acres of kingfisher habitat has been or will be disturbed for the expeditionary and permanent stationing of the THAAD missile battery and modification of the CDZ; thus, 334.7 acres will be protected to mitigate the loss of habitat due to project activities.

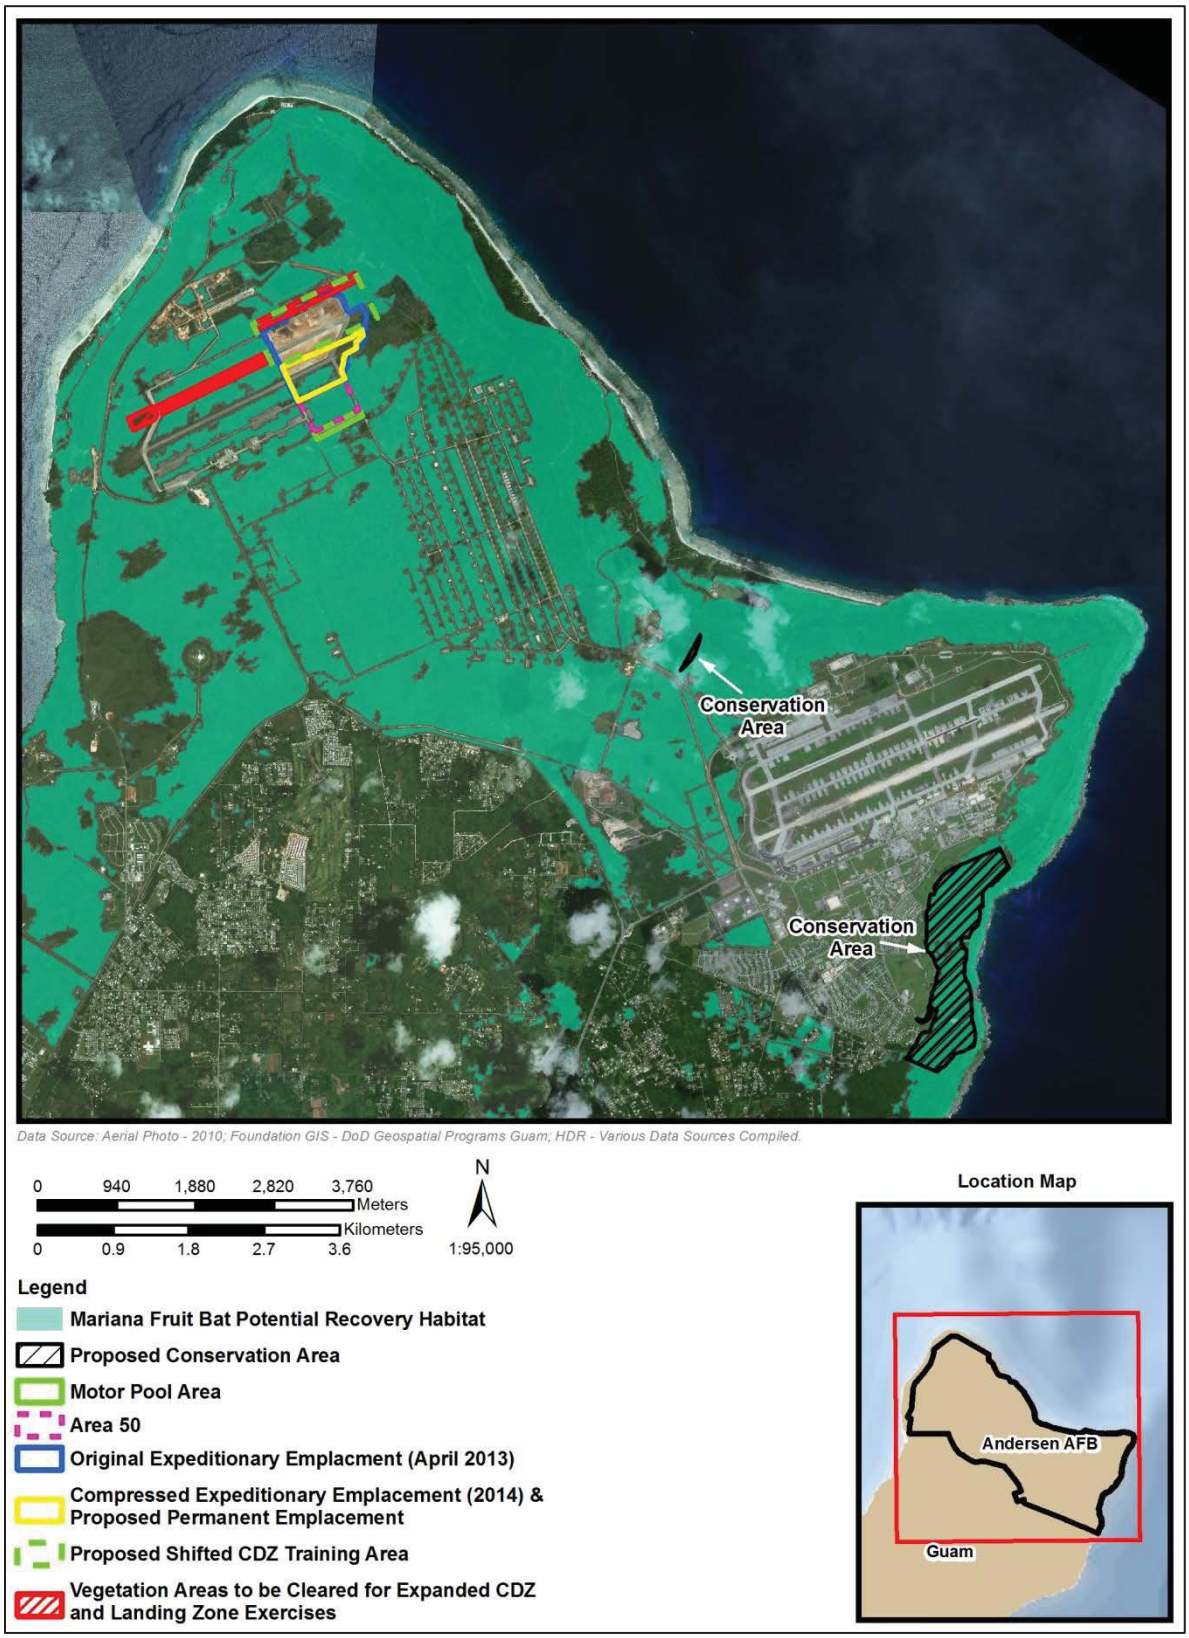

Figure 5. Potential recovery habitat for bats, indicating area proposed for conservation to mitigate impacts to listed species (taken from BA, 94th AAMDC 2016).

ANALYTICAL FRAMEWORK FOR THE JEOPARDY/ADVERSE MODIFICATION ANALYSES

Jeopardy Determination

In accordance with policy and regulation, the jeopardy analysis of this biological opinion relies on four components: (1) Status of the Species, which evaluates the range-wide condition of the species analyzed in this opinion, the factors responsible for that condition, and the survival and recovery needs of this species; (2) the Environmental Baseline, which evaluate the current condition of the species in the action area, the factors responsible for that condition, and the relationship of the action area to the survival and recovery of the species; (3) the Effects of the Action, which determines the direct and indirect impacts of the proposed Federal action and the effects of any interrelated or interdependent activities on the species; and (4) Cumulative Effects; which evaluates the effects of future, non-Federal activities in the action area on the federally listed species.

ENVIRONMENTAL BASELINE AND STATUS OF THE SPECIES

The environmental baseline describes the status of the species and factors affecting the environment of the species or critical habitat in the proposed action area during the consultation process. The baseline usually includes State, local, and private actions that affect a species at the time the consultation begins. Unrelated Federal actions that have already undergone formal or informal consultation are also part of the environmental baseline. Federal actions within the action area that may benefit listed species or critical habitat are also included in the environmental baseline.

The crow, kingfisher, and rail are all extirpated from the wild in northern Guam. However, maintaining necessary amounts of suitable habitat for eventual reintroduction is crucial to recovery of these species. This analysis looks at direct effects to species present in or near the action area as well as effects to habitat clearance and modification.

A number of recent or ongoing consultations affect the baseline and status of the species in regards to this action. They are described briefly below:

Intelligence, Surveillance, Reconnaissance – Strike (ISR Strike)
The ISR Strike action was analyzed for adverse effects to fruit bats, crows, kingfishers, and rails. Construction involved clearing approximately 180 acres and operations include aircraft flights 240 days per year as well as an increase in population of military and Air Force civilian and contractor staff (2006-F-0266) (USFWS 2006a, p. 9-11). As a conservation measure, this action was to include two ungulate exclosures, totaling approximately 494 acres to offset the loss of habitat from clearing and aircraft operations. In addition, additional staffing, native vegetation outplanting, and BTS interdiction and research were included in the project description. To date, AAFB is out of compliance with the ISR Strike BO as many conservation measures have yet to be implemented. While one ungulate exclosure, encompassing just over 300 acres, was constructed, it is slated for removal or modification for construction of a live-fire training range complex under the proposed relocation of marines to Guam, and there is no clear plan for its replacement to date.

Mariana Islands Training and Testing (MITT)
This action, formerly referred to as the Mariana Islands Range Complex (MIRC), covers most of the islands and surrounding waters of the Mariana Archipelago. Training under the MITT action includes night-time work on AAFB that results in noise disturbance. Mitigation for effects to listed species in Guam includes brown treesnake interdiction efforts. The most recent reinitiation of this action (formerly known as Mariana Islands Range Complex or MIRC) did not propose any conservation measures for listed species.

Guam Marine Relocation and Memorandum of Agreement on Micronesian Kingfisher Recovery
This consultation is currently underway following formal reinitiation in February 2016 to include effects of the action on species listed for protection under the ESA in 2015. It involves clearing 1,021 acres of recovery habitat for kingfishers, bats, and cycads; 1,016 acres of recovery habitat for crows, and 1,145 acres of recovery habitat for rails. Through a Memorandum of Agreement between the Department of the Navy (DON) and the Service, the DON pledges to manage 5,234 acres of kingfisher habitat in northern Guam. A forest enhancement site, totaling 1,213 acres (a portion of the 5,234 acres set aside in the MOA) will be fenced and managed for native plant restoration and potentially endangered animal reintroduction.

Status of the Mariana Fruit Bat

Legal Status

The Mariana fruit bat (*Pteropus mariannus mariannus*; "fanihi" in Chamorro; hereafter, fruit bat) was listed as endangered on Guam in 1984, but was downlisted to threatened in 2005 when it was determined that all fruit bats on Guam and throughout the Commonwealth of the Northern Mariana Islands (CNMI) comprise a single subspecies (USFWS 2005b, p. 1191). In 2004 critical habitat for the fruit bat was designated at the Guam National Wildlife Refuge Ritidian Unit (USFWS 2004, p. 62944).

Species Description

The Mariana fruit bat is a medium-sized fruit bat in the family Pteropodidae that weighs 0.66 to 1.15 pounds. Males are slightly larger than females. The underside (abdomen) is black to brown with gray hair interspersed that creates a grizzled appearance. The shoulders (mantle) and sides of the neck are bright golden brown, but may be paler in some individuals. The head varies from brown to dark brown. The well-formed, rounded ears and large eyes give the face a canine appearance.

Current Known Range

The Mariana fruit bat is a subspecies endemic to the Mariana archipelago (Guam and the CNMI), where it was historically present on every island except Uracas (Wiles et al. 1989, p. 69). The fruit bat is thought to be extirpated from Tinian (USFWS 2009c, pp. 269-272; USFWS 2014d, pp. 2-3).

Life History

The diet of the fruit bat is comprised of fruits, nectar, pollen, and some leaves (Wiles and Fujita 1992, pp. 26-31; Wiles and Johnson 2004, p. 591), and it uses several forest types for foraging,

roosting, and breeding, including native primary and secondary limestone forest, volcanic (or ravine) forest, old coconut plantations, and groves of *Casuarina equisetifolia* (Glass and Taisacan 1988, pp. 6–13; Worthington et al. 2001, pp. 137–138; Wiles and Johnson 2004, pp. 589–591). Most fruit bats roost during the day in maternity colonies at sites to which they show a high level of fidelity (unless disturbed). A small proportion of fruit bats, usually males, roost alone or in small groups called bachelor colonies. Fruit bats will abandon roost sites if disturbed and have been reported to move to new locations as far as 10 kilometers (km) (or 6 miles) away (USFWS 1990b, p. 9). Any fruit bat colony can be disturbed by humans close enough to be smelled; which can be up to 200 m (656 ft) away (J. Boland, pers. obs. 2009). In addition, fruit bats have flushed from maternal roosts in response to aircraft overflights on Guam with noise levels above 90 dB (SWCA 2012, p. 23, 37). When colonies are disturbed, fruit bats may be negatively affected in a variety of ways, including but not limited to, destruction of social structures, direct injury, disruption of energetic and hormonal balance, forced relocation to lower quality habitat, abandonment of non-volant young, and disruption of breeding activities (Wingfield et al. 1998, pp. 191-204; Heideman 2000, pp. 469-499; Klose et al. 2006, p. 341; CNMI 2010, p. 7).

Data is limited for age of sexual maturity, reproductive rates, length of gestation, and lifespan of Mariana fruit bats. Female bats of the family Pteropodidae generally have a gestation period of 4.6- 6.3 months and one offspring per year (Pierson and Rainey 1992, pp. 1-17). Many *Pteropus* species typically do not give birth before 18 months of age (Pierson and Rainey 1992, pp. 1-17; McIlwee and Martin 2002, p. 76). Based on these reproductive traits, several authors have suggested that *Pteropus* bats have a low maximum population growth rate and thus a slow rate of recovery when a population is diminished (Pierson and Rainey 1992, p. 1-17; McIlwee and Martin 2002, p. 76).

Population Dynamics and Status

The total population of the Mariana fruit bat is estimated to be approximately 6,000 animals (USGS 2010, p. 36; CNMI 2011, p. 6). Surveys suggest populations are stable or declining throughout most of their range. A notable exception to the declining trend is the island of Rota, where the population has increased since 2008 (CNMI 2008, p. 11; CNMI 2011, p. 6). The fruit bat population on Rota is estimated at approximately 2,600 (CNMI 2011; p. 6). Although comprehensive surveys have not been conducted on Saipan, there have been no confirmed observations of maternity colonies in recent years, and the island-wide population is expected to be less than 50 individuals (T. Willsey, CNMI Department of Land and Natural Resources (DLNR), pers. comm. 2014).

The population of fruit bats on Guam have been estimated to be less than 30 bats (SWCA 2013, pp. 19-22). The last maternal colony to exist on Guam was at Pati Point (SWCA 2013, pp. 13). However, in December 2015, fruit bats were observed within the Habitat Management Unit (HMU), in Guam. Preliminary estimates were 30 to 50 bats present within the HMU (D. Lujan, AAFB, pers. comm. 2016). The HMU is a plot on AAFB, 136 acres in area, used for experimental habitat restoration and brown treesnake control and research. It is enclosed in a snake barrier designed to allow emigration but not immigration of brown treesnakes. In addition, it is designed to exclude ungulates to enhance forest regeneration. It partially fulfills conservation measures to mitigate effects to listed species from Northwest Field Beddown (2006-I-0281) (USFWS 2006b). The HMU is approximately 2 km from the THAAD emplacement. Additional surveys were conducted by AAFB from December through February

and on February 10, 2016, two female bats were observed within the HMU, and at least 112 bats were counted at a single time (T. Mildenstein and D. Lujan, AAFB, pers. comm. 2016). However, recent attempts to locate and count the group have proved unsuccessful, and the bats may have relocated to an unknown location (J. Horeg, AAFB, pers. comm. 2016).

Interisland movement of bats is still largely unknown, however, genetic analysis by Mildenstein and Mills (2013) showed relatively low immigration rates between island; thus, interisland migration cannot necessarily be depended on to compensate for a population decline or loss on any particular island. (USFWS in review, p. 49)

Threats

The following is adapted from USFWS 2014d, pp. 4-5

- Loss or degradation of habitat because of human development and degradation by feral ungulates on multiple islands.
- Human disturbance through illegal hunting throughout their range.
- Nonnative snake predation –Brown treesnakes prey on non-volant young left at the roost during the night, thus preventing the recruitment of young bats into the breeding population. Effective control of brown treesnakes must be achieved before fruit bat population on Guam can recover. The interdiction, control, and ultimate eradication of brown treesnakes in the archipelago are the focus of major, ongoing projects, and the fruit bat is likely to benefit from these efforts in the long term. This prognosis would change drastically if the brown treesnake were to become established widely throughout the archipelago.
- Stochastic events – Typhoons and volcanic eruptions result in mortality, reduced population viability, and habitat loss. Natural disasters can be especially damaging to the viability of smaller fruit bat populations (*e.g.*, on Guam, Saipan, Aguiguan, and Maug). The significant loss of habitat on Anatahan after the volcanic eruption in 2003 resulted in the loss of a substantial fruit bat population that has not yet recovered.

Survival and Recovery Needs

- Before the Mariana fruit bat is considered for delisting, the Service proposes that stable or increasing populations should exist on three of the five southern islands (Saipan, Tinian, Aguiguan, Rota, and Guam), and six of the northern islands where Mariana fruit bats have persisted historically (Anatahan, Sarigan, Guguan, Alamagan, Pagan, Agrihan, Asuncion, and Maug; USFWS 2009a, pp. 37-39). Since publication of the draft revised recovery plan in 2009, new information on the Mariana fruit bat has resulted in changes to how we look at recovery for the species. We now consider recovery in terms of stable or increasing subpopulations of sufficient size distributed across Guam and the Mariana Islands. To meet recovery objectives, stable or increasing fruit bat subpopulations should at a minimum be distributed on the islands that currently have extant populations (USFWS *in review*). The final version of the Mariana fruit bat recovery plan is currently in review, and recovery criteria stated here may change upon completion of the final plan.
- Of the six northern islands, the only evidence for a possibly increasing population is on Asuncion (USGS 2010, p. 33). Of the five southern islands, only Rota has achieved an increasing population. Although a conservation area containing some important habitat for fruit bats was established on Rota (USFWS 2011, pp. 1), there is

not currently enough protected fruit bat habitat on Rota, Guam, Tinian, or Saipan to support substantial population recovery on any of those islands. Even if sufficient habitat is set aside in conservation to support recovery of populations, controlling illegal hunting may continue to be a challenge that limits recovery of the species.

Status of the Guam Micronesian Kingfisher

Legal Status

The Guam Micronesian kingfisher (*Todiramphus cinnamominus cinnamominus*; "sihek" in Chamorro; hereafter, referred to as kingfisher) was listed under the ESA as endangered in 1984 (USFWS 1984, 9 pp.). A revised recovery plan for the kingfisher was completed in 2008 (USFWS 2008a, 117 pp.). On October 28, 2004, the Service designated critical habitat for the kingfisher on approximately 376 ac (152 ha) in the fee simple portion of the GNWR (USFWS 2004, 117 pp.).

Species Description and Current Known Range

The kingfisher is endemic to the island of Guam in the Mariana Islands. The Guam subspecies is a small, sexually dimorphic forest kingfisher (Baker 1951, pp. 227–228). The adult male has a cinnamon-brown head, neck, upper back, and underparts with a black line extending around the back of the neck and the eye ring is black. The adult female resembles the male except that the upper breast is paler, as are the chin and throat, with the rest of the underparts and underwing coverts white (Jenkins 1983, p. 21). Immature birds have the crown washed in greenish-blue, and a whitish chin and throat. Underparts are buffy-white in the immature male, but may be paler in the female (Jenkins 1983, p. 21).

The kingfisher is extirpated in the wild on Guam but persists in captivity at the Guam DAWR facility and 24 U.S. mainland zoos and institutions. In response to the decline of Guam's native birds in the 1980s, the Association of Zoos and Aquariums (AZA) initiated the Guam Bird Rescue Project. Between 1984 and 1986, 29 kingfishers were translocated from Guam to zoos in the U.S. mainland to start a captive breeding program. The breeding program has been managed under the auspices of the AZA's *Micronesian Kingfisher Species Survival Plan* (Bahner et al. 1998, 54 pp.).

Life History

In the wild, kingfishers nest in cavities and feed primarily in mature, second growth limestone forest, and, to a lesser degree, in scrub limestone forest (Jenkins 1983, pp. 22–23). Kingfishers are also known to use coastal strand vegetation containing coconut palm as well as riparian habitat. However, Jenkins (1983, p. 22) reported the kingfisher was probably most common along the edges of mature limestone forest. Few data exist about specific nest sites of the kingfisher in the wild, but in one study in northern Guam (Marshall 1989), 16 nest sites were correlated with closed canopy cover and dense understory vegetation. Kingfishers nest in cavities that are excavated from the soft, decaying wood of standing dead trees (Marshall 1989, p. 475).

The breeding season for this species on Guam is reported to range from December to June, however, within the managed population (in captivity) we have seen reproduction in all months of the year with January through July being the prime breeding period. During the breeding

season, it is important to minimize disturbance within the territorial range of breeding pairs. Based on experience with the managed population, Guam kingfishers are especially sensitive to stress which would likely be increased by noise and disturbance, and compounded during the breeding season (B. Bahner, Philadelphia Zoo, pers. comm. 2015). Additionally, anything that disrupts the availability of prey items in their territory would be detrimental would negatively affect kingfishers. There is no known recommended buffer around active kingfisher nests; however in captivity nesting kingfishers have sometimes been monitored by cameras to avoid disturbing breeding birds (Bahner et al. 1998).

In the wild, the kingfisher is known to feed on invertebrates and small vertebrates, including insects, segmented worms, hermit crabs, skinks, geckoes, and possibly other small vertebrates (Marshall 1989, p. 210; Baker 1951, pp. 228–229; Jenkins 1983, p. 23).

Records of kingfisher distribution and intraspecific territorial behavior suggest this species maintains exclusive year-round territories in the wild (Jenkins 1983). Pohnpei kingfishers defend their approximately 8.1 hectare (20 ac) territories from conspecifics (Kesler and Haig 2007a, pp. 386-387). Kesler and Haig (2007b, pp. 769–770) determined that kingfisher home ranges on Pohnpei consist of mixed forest and open areas and at least part of this area includes mature forest. It should be noted that Guam Micronesian kingfisher territories may differ from Pohnpei Micronesian kingfisher territories due to differences in forest structure (Mueller-Dombois and Fosberg 1998, pp. 269–275, 288–291). However, information on the related Pohnpei kingfisher as a surrogate species to the Guam Micronesian kingfisher represents the best available scientific information on kingfisher territory size and home ranges in the Pacific islands to date.

The life expectancy of the kingfisher in the wild is unknown. However, in captivity, males have a longer lifespan (23 years) than do females (15 years). Both males and females can reproduce at 1 year of age. In captivity, males have been observed to breed as old as 19 years, while females have not been observed to breed beyond the age of 12 (AZA 2014, p. 4).

Current Status

The kingfisher is currently extirpated from the wild. It was considered “fairly common” and occurred throughout forested areas on Guam in 1945 (Baker 1951, p. 229). Populations in southern and central Guam disappeared by the 1960s (Jenkins 1983, p. 25). The northern Guam population subsequently declined rapidly, and by 1985, fewer than 30 individuals were recorded on Guam (Marshall 1989, p. 474) and the taxon was considered extirpated from the wild by 1988 (Wiles et al. 2003, p. 1,354). Predation by the brown treesnake is considered the main cause of the decline of the kingfisher population on Guam (Savidge 1987, USFWS 2008a, p. iv). Currently, the captive population consists of 155 adult kingfishers (86 males and 69 females) in captive rearing facilities (GMKF Recovery Team 2015, p.3). The current captive population was founded by 16 of the 29 individuals brought into captivity. The current gene diversity is 87.74 percent; with the potential to reach 92.45 percent (AZA 2014, p. 4).

Threats

The Service intends to reintroduce the kingfisher into the wild on Guam. For that effort to be successful, the following threats need to be addressed. The following discussion is adapted from USFWS 2014a, p. 2:

- Loss or Degradation of Habitat
  - Incremental habitat loss due to fire, especially in southern Guam (Department of Agriculture 2010), and urban and agricultural development is increasingly threatening the long-term conservation of the kingfisher because of the continued loss of habitat on Guam.
  - Ongoing and proposed plans by DoD to expand training and operations on Guam are threatening much of the remaining kingfisher habitat.
  - The persistence of large, feral ungulate populations is likely to further degrade remaining forest habitats, thus lowering their value for kingfisher recovery.

- Predation
  - Predation risk from brown treesnakes currently prevents effective reintroduction of the kingfisher to Guam.

- Stochastic Events
  - Typhoons will continue to degrade forest and the affected forest areas may require several years to regenerate.
  - Although birds in the Mariana Islands have evolved with typhoons, typhoons in concert with low population numbers, habitat loss, and behavioral and genetic consequences of captive breeding could negatively affect the recovery of the Guam Micronesian kingfisher.
  - Climate models indicate that hurricanes in the northwestern Pacific are expected to increase in intensity, frequency, and duration by 2200 and continue to increase further into the future (Emmanuel et al. 2008, p. 360). These storm increases will likely have a significant effect on habitat and survival of listed species on Guam.

Survival and Recovery Needs

The recovery plan (USFWS 2008a) for the kingfisher calls for a total viable population of 2,000 adult kingfishers on Guam within two subpopulations of 1,000 adults each. One subpopulation would be located in northern Guam, and one subpopulation would be located in southern Guam to reduce the risk of a second extirpation event due to random, stochastic events. Based on acreage estimates for breeding pairs and non-breeding adults, the total habitat needed to support 1,000 adults (500 breeding pairs) is 10,462 acres.

Each subpopulation must have brown treesnakes and other predators controlled to a level where establishment of a sustainable kingfisher population is feasible and habitat to support this population level must be protected and managed. In the interim, the kingfisher also may need to be established in the wild on other islands outside their native range to reduce the detrimental consequences of long-term captivity and to spread the risk from stochastic events. Although any population(s) established on other islands outside of the kingfisher's historical range would be considered temporary and would not contribute toward the recovery goal of two subpopulations of 1,000 adults each on Guam, the ability to translocate wild birds versus captive birds to Guam would increase success of their recovery and survival on Guam. However, ultimately the recovery of the kingfisher is dependent on having adequate protected habitat free of threats on Guam to provide for the two subpopulations.

New management actions that have occurred in the last five years include:

- In 2014, the USDA-APHIS Wildlife Services, in coordination with the National Wildlife Research Center, the DoD-Environmental Security Technology Certification Program, and the Department of Interior-Office of Insular Affairs, conducted a test of aerial application of a brown treesnake toxicant (acetaminophen) over forested areas in AAFB (Dorr et al. 2014, unpublished data). The results of this study indicate that development of a scalable automatic bait application system could be used in the near future for large landscape scale brown treesnake control and suppression (Dorr et al. 2014, unpublished data).
- Brown treesnake eradication and control using an aerial automated broadcast system using acetaminophen, as a toxicant to the snake, is being planned for testing in Andersen South, Guam. The knowledge gained from this study may result in findings that would support efficient delivery of acetaminophen to snakes on Guam for a landscape level treatment.
- The Guam Micronesian kingfisher recovery team is developing a release plan on other islands outside the kingfisher's historical range to reduce the negative consequences of long-term captivity. A successful release will reduce our reliance on captive propagation for ensuring the continued existence of the kingfisher, and this population can serve as a source for translocating birds to Guam, once the threat of brown treesnakes has been sufficiently controlled.
- Construction of a 312-ac (112-ha) ungulate exclosure fence at Northwest Field on AAFB by DoD per biological opinion requirements (USFWS 2006a). However, DoD has proposed to build the proposed LFTRC within this mitigation site, which is also located on Overlay Refuge.
- Construction of the 136-ac (55-ha) Habitat Management Unit (HMU) brown treesnake and ungulate exclosure fence at Anderson Air Force base. Ungulate removal within the HMU is near completion by DoD per a section 7 consultation requirement (USFWS 2006b).
- Construction of a multi-species exclosure fence within the fee simple portion of the GNWR at Ritidian Point, Guam.
- Construction of 4,400 ft of coated chain link fence along Route 2A on the perimeter of NBG by DoD per biological opinion requirements (USFWS 2010). The fence provides an ungulate exclosure for the 3,114 ac (1,260 ha) of the main base of NBG. The fencing project is intended to effectively close off Orote peninsula from any new ungulate incursions and only entry control gates will be left unfenced. Ungulate removal within NBG is ongoing.

Recommendations for Future Actions (adapted from USFWS 2008a; USFWS 2014a, p. 3):

- Maintain or increase genetic diversity in the captive kingfisher population by implementing management strategies to exploit the potential gene diversity in the captive populations at the DAWR and AZA facilities.
- Predator Monitoring and Control
    - Continue efforts to develop and refine brown treesnake control techniques and support small-scale and large-scale control and/or eradication efforts on Guam.
- Reintroduction / Translocation

  - Develop a reintroduction plan for the kingfisher on Guam and set aside and protect recovery areas to facilitate its de-listing as soon as possible following the reintroduction of the kingfisher on Guam.

- Protection and restoration of kingfisher recovery habitat, including permanent protection as conservation areas and fencing to exclude brown treesnakes and ungulates.

Status of the Mariana Crow

Legal Status

The Mariana crow ("aga" in Chamorro) was listed as endangered throughout its range in 1984 and critical habitat was designated on Guam and Rota (USFWS 1984, pp. 33881-33885; 2004, pp. 62944-62990). On October 28, 2004, the Service designated critical habitat for the Mariana crow on approximately 376 ac (152 ha) in the fee simple portion of the GNWR (USFWS 2004, 117 pp.).

Species Description and Known Range

The Mariana crow is the only member of the genus *Corvus* occurring in Micronesia (Jenkins 1983, p. 25). This species is known historically only from the islands of Rota and Guam, but is now extirpated from Guam. Preliminary genetic studies indicate that the Rota population is most likely a genetic subset of the Guam population (Tarr and Fleischer 1999, p. 946).

Life History and Population Dynamics

Mariana crows are omnivorous, and their diet includes a wide variety of plants and animals, including insect larvae, centipedes, grasshoppers, mole crickets, praying mantis, earwigs, hermit crabs, skinks, geckos, and bird eggs (Jenkins 1983, p. 26, 31; Tomback 1986, p. 399; Ha and Ha 2010a, pp. 8-10; Faegre *in press*).

Mariana crows use forested habitats including limestone, strand, ravine, agricultural forests, and secondary forests (Jenkins 1983, p. 25, 32). However, evidence suggests they are most abundant in native limestone forests (Morton et al. 1999, p. 13, 41;) and nests are found exclusively in native trees in closed canopy forests (Morton et al. 1999, p. 13, 33; Ha et al. 2011, 2012, and 2013, pp. 32, 25, and 24-31, respectively).

Breeding likely occurs all year on Rota, while peak nesting activity generally occurs between August and February (Morton et al. 1999, p. 12; Ha et al. 2013, p. 31). A minimum of 65 days is necessary to build the nest, incubate the eggs, and rear the brood through fledging (Morton et al.1996, p. 21). Mariana crows generally produce only a single brood per year; however, nest failure and other factors lead to multiple nest attempts each breeding season.

Little is known regarding lifespan, age of sexual maturity, and length of reproductive life in Mariana crows. The oldest known wild crow was at least 18 years old when last observed on Rota in 2014 (A. Kroner and S. Faegre, University of Washington, pers. comm. 2014). This same adult male was at least 17 years old when he was last seen feeding a fledgling in 2013. Another male was 14 years old when he last produced a chick in 2009, and a 15-year-old female was observed with a fledgling in 2014 (S. Faegre, University of Washington, pers. comm. 2014).

Although it was originally thought that Mariana crows begin breeding around 3.5 years old (Morton et al. 1999, p. 2), a radio-tagged male Mariana crow built his first nest at 16 months of age and was observed feeding a fledging at 21 months of age. Two other banded crows, a female and a male, successfully fledged young in 2011 and 2013, just after they turned two years old (A. Kroner and S. Faegre, University of Washington, pers. comm. 2014).

Mariana crows are known to be highly susceptible to disturbance from human activities (Morton 1996, p. 60, 62, 72; Ha, R. 2015, pers. com.; Ha et al. 2011, p. 5). Ha et al. (2011, p. 236) found that nest sites were always greater than 300 meters from any buildings, and that actual nest sites were almost twice as far from roads and buildings as random sites.

Distribution, Status, and Threats

Guam

Although the Mariana crow was once present throughout Guam (Baker 1951, p. 246), the population has been declining since at least the 1960's (Engbring and Ramsey 1984, p. 30; Engbring et al. 1986, p. 92) and is now extirpated. The last known crow of Guam origin was observed in 2001, and the last known wild Mariana crow that was captive-reared from Rota and released on Guam was observed in 2012 (J. Quitugua, DAWR, pers. comm. 2014). Predation by brown treesnakes is the overriding factor in the extirpation of Mariana crows from Guam (USFWS 2005a).

Suitable habitat for Mariana crows is still present on Guam. As described below in the Environmental Baseline for the Mariana Crow, we estimate that 24,919 acres (10,084 ha) of Mariana crow habitat is left on Guam. More information on crow habitat is provided in the Environmental Baseline for the Mariana Crow section below.

Rota

In 1976, Mariana crows were considered relatively common and widely distributed on Rota (Pratt et al. 1979, p. 234). Reanalysis of the first island-wide survey for the species on Rota in 1982 using current density estimate methods resulted in a population estimate of 1,491 birds (815-3115 birds, 95 percent confidence interval) (Engbring et al. 1986, pp. 92-95; F. Amidon, Service, pers. comm. 2014). The most recent island-wide pair survey on Rota was conducted during the 2013 breeding season and documented 46 breeding pairs; an approximate 94 percent decrease in the population since 1982 (Kroner 2014, p. 3). The primary threats to the Mariana crow on Rota are suspected to be predation by cats, human persecution, and habitat destruction (USFWS 2014b, p. 3), but evidence is limited and substantially more research is needed.

Mariana crow telemetry studies were conducted from 2009-2013 and will begin again in the 2014-2015 nesting season. Before telemetry studies began on Rota there was no evidence available to suggest feral cats (*Felis silvestris*) were predating crows. The lack of evidence was likely due to high scavenging and decomposition rates, and the extreme unlikelihood of finding a fresh carcass in time to retrieve any useful information regarding cause of death. Since telemetry efforts began, nine recently-deceased, radio-tagged Mariana crows have been found with evidence suggesting cat predation, and one untagged adult was taken in for care and later died after receiving what a veterinarian confirmed as an infected cat bite (Ha et al. 2013, pp. 5-6).

Recovery Criteria for the Mariana Crow

The following criteria are taken from the Draft Revised Recovery Plan for the Mariana Crow (USFWS 2005a).

- The Mariana crow may be considered for downlisting from endangered to threatened status when all of the following criteria are met:
    - Mariana crow occur in two populations, one on Rota consisting of a minimum of 75 territorial pairs, and 1 in northern Guam consisting of a minimum of 75 territorial pairs;
    - Both populations are stable or increasing based on quantitative surveys or demographic monitoring that demonstrates an average intrinsic growth rate (λ) not less than 1.0 over a period of at least 10 consecutive years;
    - Sufficient Mariana crow habitat, based on quantitative estimates of territory and home range size, is protected and managed to achieve criteria 1 and 2 above;
    - Brown treesnakes and other introduced predators found to be a threat to Mariana crow are controlled at a sufficient level to achieve criteria 1 and 2 above;
    - Brown treesnake interdiction efforts are in place to prevent the establishment of brown treesnakes on Rota; and
    - Efforts to resolve Mariana crow and landowner conflicts have been implemented.

- The Mariana crow may be removed from the Federal list of threatened and endangered species when all of the following criteria are met:
    - Mariana crow occur in three populations, one on Rota consisting of a minimum of 75 territorial pairs, one on northern Guam consisting of a minimum of 75 territorial pairs, and one in southern Guam consisting of a minimum of 75 territorial pairs;
    - All three populations are stable or increasing based on quantitative surveys or demographic monitoring that demonstrates an average intrinsic growth rate (λ) not less than 1.0 over a period of at least 10 consecutive years;
    - Sufficient Mariana crow habitat, based on quantitative estimates of territory and home range size, is protected and managed to achieve criteria 1 and 2 above;
    - Brown treesnakes and other introduced predators are controlled at a sufficient level to achieve criteria 1 and 2 above;
    - Brown treesnake interdiction efforts are in place to prevent the establishment of brown treesnakes on Rota;
    - Efforts to resolve Mariana crow and landowner conflicts have been implemented; and
    - A monitoring plan has been developed and is ready for implementation, to cover a minimum of five years post-delisting, to ensure the ongoing recovery of the species and the continuing effectiveness of management actions.

Since the draft revised recovery plan was published in 2005, additional work on population viability of the Mariana crow has occurred. This recent assessment of population viability indicated that 75 territorial breeding pairs may not be viable over the long-term and that 100 territorial breeding pairs may be a more appropriate recovery target (Amidon 2012, unpubl. data).

Survival and Recovery Needs on Guam

Management and recovery actions that have occurred in the last five years include:

- Construction of a 312-ac (112-ha) ungulate exclosure fence at Northwest Field on AAFB by DoD per biological opinion requirements (USFWS 2006b). However, the DON has proposed to build the proposed LFTRC within this mitigation site, which is also located on Overlay Refuge.
- Construction of the 136-ac (55-ha) Habitat Management Unit (HMU) brown treesnake and ungulate exclosure fence at AAFB. Ungulate removal within the HMU is near completion by DoD per a section 7 consultation requirement (USFWS 2006b).
- Construction of a multi-species exclosure fence within the fee simple portion of the GNWR at Ritidian Point.
- Construction of 4,400 ft of coated chain link fence along Route 2A on the perimeter of NBG by DoD per biological opinion requirements (USFWS 2010). The fence provides an ungulate exclosure for the 3,114 ac (1,260 ha) of the main base of NBG. The fencing project is intended to effectively close off Orote peninsula from any new ungulate incursions and only entry control gates will be left unfenced. Ungulate removal within NBG is ongoing.
- In 2014, the USDA-APHIS Wildlife Services, in coordination with the National Wildlife Research Center, the DoD-Environmental Security Technology Certification Program, and the Department of Interior-Office of Insular Affairs, conducted a test of aerial application of a brown treesnake toxicant (acetaminophen) over forested areas in AAFB (Dorr et al. 2014, unpublished data). The results of this study indicate that development of a scalable automatic bait application system could be used in the near future for large landscape scale brown treesnake control and suppression (Dorr et al. 2014, unpublished data).

Recovery actions still needed to allow the reintroduction of the Mariana crow to Guam

- Development and implementation of large-scale, long-term methods for brown treesnake control that will reduce the brown treesnake population on a landscape level.
- Protection and restoration of Mariana crow habitat in northern and southern Guam including in-perpetuity protection as conservation areas and fencing to exclude brown treesnakes and ungulates.
- Continued management of the fenced exclosures at Northwest Field, the HMU, and NBG as described above.

Status of the Guam Rail

Legal Status

The Guam rail (*Gallirallus owstoni*; ko'ko' in Chamorro; hereafter, rail) was listed as endangered on Guam in 1984 (USFWS 1984, pp. 2485-2488). An experimental, nonessential population of rails occurs on Rota. The rails on Rota are treated as threatened species, rather than as endangered species, for the purposes of sections 4(d) and 9 of the ESA (USFWS 1989, pp. 43966-43970). Critical habitat for the rail has not been designated on Guam.

Species Description and Current Known Range

The Guam rail is endemic to the island of Guam in the Mariana Islands. The species is derived from the closely related barred rail (*Gallirallus torquatus*) of the Philippines and Indonesia (Ripley 1977). No closely related species occur in Micronesia. The rail is medium-sized and capable of short burst of flight (1 to 2 m), but is seldom observed in flight (Jenkins 1979, p. 404). Rails are about 28 cm (11 in) in total length (Taylor 1998, p. 258). Guam rails have elongated and laterally compressed, particularly in the neck and breast regions, bodies allowing the birds to move rapidly through dense vegetation.

The rail is extirpated in the wild on Guam but persists in captivity at the Guam DAWR facility and twelve U.S. mainland zoos (AZA 2014, p. 1). Efforts to establish a nonessential experimental population on the island of Rota has been underway since 1989. The establishment of a wild population on Rota will ensure that a source wild population is available for future repatriation of rails to Guam when brown treesnakes have been controlled or eradicated on Guam (USFWS 1989, p. 43967). On Cocos Island (a small islet approximately 1.6 km (1 mi) off the southern coast of Guam), breeding pairs of rails have become established in a predator-controlled habitat through efforts associated with a Safe Harbor Agreement and activities permitted under section 10(a)(1)(A) of the ESA (USFWS 2008b; USFWS 2008c, p. 1-2). This agreement, signed in 2008, has allowed for the establishment of Guam rails on private land owned and managed by Cocos Island Resort and public land owned by the Government of Guam and managed by the Guam Department of Parks and Recreation. The rails are monitored to learn more about survivorship, breeding behavior, habitat preference and nesting success.

Life History

The Guam rail formally occurred in most habitat types on Guam, including forest, savanna, secondary grassland, agricultural areas, mown grass bordering scrub communities, mixed woodland and scrub, and fern thickets (Jenkins 1979, p. 405-406; Taylor 1998, p. 259). Guam rails were predominantly observed using scrubby secondary growth area and the edges of mixed forest areas (Jenkins 1979, Engbring and Ramsey 1984). Jenkins (1979) reports that they were seldom observed in the interior of mature limestone forests or savanna areas and did not occur in wetlands. As Guam was probably mostly limestone forest before the arrival of humans (Forsberg 1960), the rail may have become more common after much of the mature forest had been converted to scrubby second-grown or mixed forest (Engbring and Ramsey 1984).

The diet of the Guam rail is comprised of snails, slugs, lizards, insects, and vegetable matter such as seeds and palm leaves; the rail feeds on food items from the surface of the ground, especially snails and slugs after rain showers (Jenkins 1979, pp. 405-406). They are able to forage at night, but are most active during the dawn and dusk (Jenkins 1979, p. 404-406; Taylor 1998, p. 259).

Guam rails are monogamous and breed throughout the year (Jenkins 1979, p. 406; USFWS 1990a, p. 9), with a possible peak breeding period during the rainy season (May-October) (Perez 1969 as cited in the USFWS 1990a, p. 9). They can lay two to four eggs per clutch and both parents share in the construction of the nest. Nests are located on dry ground in dense grass, are a shallow cup of interwoven loose and rooted grass, and are built by both sexes (Jenkins 1979, p. 406; Taylor 1998, p. 260).

In captivity, Guam rails can live up to 17 years, while females can reach 16 years old. Median life expectancy for captive males is 9.5 years; captive female median life expectancy is slightly lower at 5.7 years (AZA 2014, p. 5). The median life expectancy of Guam rails in the wild is unknown. Both males and females can begin reproducing at approximately 5 months old. Males have bred until the age of 11, and females as old as 9 years old have successfully reproduced. Breeding in captivity is complex, as males can be extremely aggressive and have at times injured or killed females. In captivity, clutch sizes range from one to six eggs, averaging 2.1 eggs, with an incubation period of 19 days.

Population Dynamics and Status

Guam rails were once distributed throughout Guam (USFWS 1990a, p.7). They first disappeared from southern Guam in the early 1970's (Jenkins 1979). In 1981, the population was reduced to approximately 2,300 individuals and only existed in northern Guam (Engbring and Ramsey 1984, p. 28). In 1983, estimates of the population size indicated that fewer than 100 individuals remained on Guam and 22 individuals were moved to captive propagation facilities (Haig and Ballou 1995, p. 446). The rail was extirpated on Guam by 1987 (Wiles et. al. 1995, p. 38).

There have been two releases of rails on Guam since this species has been listed as endangered. In 1998, 16 rails were released in "Area 50" at AAFB in northern Guam (Beauprez and Brock 1999). A temporary brown treesnake barrier was constructed around Area 50 and snake populations in the barrier were reduced through snake control. Breeding was documented, although the small population was extirpated by predators, mainly feral cats. In 2003, a second release of 44 rails occurred in a brown treesnake-reduced area of the Munitions Storage Area on AAFB (P. Wenninger, DAWR, pers. comm. 2008). Efforts to reduce cat predation on the rails were limited due to difficulty in obtaining approval to control cats in the area. By 2008, rails no longer were present in the Munitions Storage Area (P. Wenninger, DAWR, pers. comm. 2008; USFWS 2009b, p. 5).

On Rota, over 800 captive-bred Guam rails have been released between 1989 and 2008 in an effort to establish an experimental wild population (Beck 1991, Brock and Beck 1995, Beauprez and Brock 1996-1999a, P. Wenninger, DAWR, pers. comm. 2008). The introduction to the island of Rota, which is outside the historical range of the species, was justified because primary habitat on Guam had been altered through the establishment of the introduced, predatory brown treesnake (USFWS 1989, p. 43966). Improvements in managing the captive flock have increased the number of rails available for each release and the larger release cohorts have increased the likelihood of population establishment. Population estimates in 2002 indicated 100 rails were present on the northeast end of Rota near two release sites, Duge and Saguagaga. Based on surveys conducted in July 2013, there are approximately 125 rails on Rota (S. Medina, DAWR, pers. comm. 2013). However, released birds still suffer mortality primarily due to feral cat predation, which slows population establishment. Current release strategies include intensive cat trapping and a review and update of monitoring protocol for rails on Rota.

On Cocos Island, sixteen captive bred rails were released in November 2010. Prior to the release, rats (*Rattus* spp.) were eradicated on Cocos Island. Guam rails are successfully breeding (16 nests and 12 chicks have been observed) on Cocos Island. Sightings of unbanded adults have been documented, which suggests that chicks are surviving into adulthood (S. Medina, DAWR, pers. comm. 2013).

As of December 30, 2014, the Guam rail captive population is distributed among 14 institutions, with the Guam DAWR facility holding 116 birds and the 13 Association of Zoos and Aquariums (AZA) facilities housing 46 birds. At that time, current gene diversity was 88 percent in the DAWR facility and 83 percent at the AZA facilities (AZA 2014, p. 4). When gene diversity falls below 90 percent in a founding population, it is expected that reproduction will be compromised by, among other factors, lower hatch rates, small clutch sizes, and greater neonatal mortality (Ross et al. 2006). However, there still remains the potential to increase the gene diversity in DAWR and AZA facilities over the long term (AZA 2014, p. 6). The DAWR and AZA work cooperatively and closely coordinate on the transfer of birds to facilities, as needed, in order to manage the genetic diversity within the captive Guam rail population (AZA 2014, p. 4). These facilities also support the releases of individuals into the wild on Rota.

Threats (adapted from USFWS 2014c, p. 2-5):

- Loss or degradation of habitat –
    - Agricultural and urban development is a factor in habitat loss and degradation on Guam.
    - Nonnative snake predation. The brown treesnake continues to limit efforts to reestablish rails on Guam.
    - Cat predation. Feral cats continue to limit efforts to reestablish rails on Guam and impact the rail experimental population on Rota.
    - Rodent predation. Because rats have been eradicated and are absent from Cocos Island, there is continued efforts to prevent the reintroduction of rats to this island. Rats can negatively impact rails by consuming eggs and preying on chicks.
    - Stochastic events – Although birds in the Mariana Islands have evolved with typhoons, typhoons in concert with low population numbers, habitat loss, and behavioral and genetic consequences of captive breeding could negatively affect the recovery of the Guam rail.

Survival and Recovery Needs

Before the Guam rail is considered for downlisting from endangered to threatened, the repatriation of 1,000 birds to northern Guam and 1,000 birds to southern Guam (total = 2,000 individuals; USFWS 1990a, p. 33) would need to occur and brown treesnakes would need to be controlled on Guam (USFWS 1990a, p. 33-34). No criteria were defined for delisting. Traill et al. (2009) proposed a minimum population target of 5,000 individuals as an appropriate target for species conservation.

New management actions that have occurred in the last five years include:

- Brown treesnake eradication and control using acetaminophen, as a toxicant to the snake, is being conducted within the approximately 136-acre (55-hectare) Habitat Management Unit on AAFB. The project may result in the reduction of snake numbers to a low enough level to allow for rails to survive and reproduce within this snake-proofed area on Guam.
- Management unit planning – On Guam, a management plan is currently being developed for the HMU on AAFB. The plan will consider the reintroduction of Guam rails to this site.
- Predator control – Cat control is conducted on Rota and will continue with increased efforts from additional funding by the Service in fiscal year 2015.

Recommendations for Future Actions (adapted from USFWS 2014c, p. 3):

- Maintain or increase genetic diversity in captive rail population – Implement management strategies to exploit the potential gene diversity in the captive populations at the DAWR and AZA facilities.
- Predator monitoring and control
    - Continue efforts to develop and refine brown treesnake control techniques and support small-scale and large-scale control and/or eradication efforts on Guam.
    - Continue and increase efforts to control and eradicate brown treesnakes on Guam and prevent introduction of brown treesnakes on other Mariana Islands.
    - Implement large-scale cat control and/or eradication.
- Reintroduction / translocation
    - Consider alternative sites for establishing other experimental populations.
    - Develop reintroduction plan for Guam rails on Guam and set aside and protect recovery areas for these rails on Guam.
- Revise recovery objectives and criteria – Revise recovery plan.
- Population monitoring and viability analysis – Continue population and demographic monitoring on Rota and Cocos Island.

Protection and restoration of Guam rail recovery habitat including in-perpetuity protection as conservation areas and fencing to exclude brown treesnakes and ungulates.

Status of *Cycas micronesica*

Legal Status

Cycas micronesica (or "fadang" in Chamorro) occurring within the Mariana Islands was listed as threatened under the ESA in 2015 (USFWS 2015b, 73 pp.). No critical habitat has been designated for this species. A recovery plan for *C. micronesica* has not been completed.

Species Description and Current Known Range

Cycas micronesica is a palm-like, usually unbranched tree in the Cycadaceae family (Raulerson and Rinehart 1991). Adult trees can reach heights of 6 meters and fronds can reach 1 to 2.5-m long (Stone 1970, p. 65; Raulerson and Rinehart 1991, p. 4). It is known from Guam, Rota, Tinian, and Pagan (Mariana Islands); as well as Palau (politically the independent Republic of Palau) and Yap (geographically part of the Caroline Islands; politically part of the Federated States of Micronesia, in the forest ecosystem (Hill et al. 2004, p. 280; Keppel et al. 2008, p. 1,006; Cibrian-Jaramillo et al. 2010, pp. 2,372-2,375; Marler 2013, in litt.; DON 2015 pp. 3-140).

Currently, there are 15 to 20 occurrences of *C. micronesica* totaling 900,000 to 950,000 individuals on the Micronesian Islands of Guam, Rota, Yap, and Palau. There are a small number of individuals on Pagan (DON 2015, pp. 3-136 – 3-137) and 1,000 individuals present on Tinian (DON 2014, in litt.). On Guam and Rota, there are fewer than 630,000 (T. Marler, UOG, pers. comm. 2013). This number does not distinguish between successfully reproducing adults and juveniles (T. Marler, UOG, pers. comm. 2013), which, because of the effects of the cycad aulacaspis scale (*Aulacaspis yasumatsui*), implies that the number of extant individuals that can successfully reproduce is much lower. On Guam, there are four fragmented occurrences, totaling fewer than 516,000 individuals: one occurrence along the shoreline to the base of the limestone

cliffs on the north side; a second occurrence beginning at the forest edge along the cliffs and continuing into the forest on the north side; a third occurrence on the northern plateau; and a fourth occurrence along the ravines and rock outcrops on the southern side, with a few individuals occurring across the savanna.

On Rota, there are four known occurrences within the forest ecosystem, totaling fewer than 111,500 individuals (Marler 2013, in litt.). On the northeast shore the first occurrence totals fewer than 25,500 individuals; the second occurrence, on the northwest shore, totals fewer than 21,600 individuals; the third occurrence on the south shore totals fewer than 63,600 individuals; and the fourth occurrence on Wedding Cake peninsula totals fewer than 300 individuals.

Life History and Ecology

Cycas micronesica is the only native gymnosperm in the Mariana Islands. Cycads are dioecious, and both sexes bear reproductive structures that are relatively massive amongst gymnosperms (*e.g*. conifers). Approximately 300 cycad species and subspecies exist across much of the tropics and subtropics, but cycads remain the most threatened group of plant species on earth (Donaldson 2003, p. 1). *C. micronesica* (sometimes considered *Cycas circinalis* in early references) occurs in limestone forests in Guam and Rota, with a smaller number of occurrences in volcanic soils typical of southern Guam (Stone 1970, p. 65). Few studies exist that describe cycad natural history and ecology in the Mariana Islands, and much of the current literature is focused on its decline and effects from introduced pests. However, *C. micronesica* is a food source for fanihi (*Pteropus mariannus mariannus*), which feed on its fruits (Wiles and Fujita 1992, p. 27), as well as for the Chamorro people, who process the fruits to rid the naturally-occurring toxins (Safford 1905, p. 71). Most cycads have historically been assumed to be wind pollinated, but recent research on a number of species has revealed that insects play in important role in pollination (Hall et al. 2004, p. 334; Kono and Tobe 2007, p. 853), even emitting chemical cues to attract pollinator insects (Schneider et al. 2002, p. 285). *C. micronesica* cones emit strong smells when pollen is mature (Raulerson and Rinehart 1991, p. 4), and evidence indicates pollination by both insects and wind (Terry et al. 2009, p. 96).

Population Dynamics and Current Status

Just 10 years ago, *Cycas micronesica* was ubiquitous on the island of Guam, and similarly common on Rota. It was the most abundant tree in Guam forest inventory surveys in 2002 (Donnegan et al. 2004, p. 16). *C. micronesica* is currently under attack by a nonnative insect, the cycad aulacaspis scale (*Aulacaspis yasumatsui*) is causing rapid mortality of all life stages of the plant (Marler 2014, in litt.). As of January 2013, *C. micronesica* mortality reached 92 percent on Guam, and cycads on Rota are experiencing a similar fate from the cycad aulacaspis scale (Marler 2013, in litt.; USFWS 2015b, p. 59435). All seedlings of *C. micronesica* in a study area were observed to die within 9 months of infestation by *A. yasumatsui* (Marler and Muniappan 2006, p. 3; Marler and Lawrence 2012, p. 233; Western Pacific Tropical Research Center (WPTRC) 2012, p. 4; Marler 2013, pers. comm.).

As mentioned above, there are fewer than 630,000 on Guam and Rota. However, this number does not distinguish between successfully reproducing adults and juveniles (T. Marler, UOG, pers. comm. 2013). Because the scale causes mortality of all life stages of *Cycas micronesica*, it prevents reproduction and recruitment into the population on Guam and Rota (USFWS 2015b, p. 59435). The cycad aulacaspis scale is not present on Tinian and Pagan. Overall, the population of *C. micronesica* is in declining because of the scale and other threats (see below).

Threats

Adapted from USFWS 2015b (p. 59435).

- *Cycas micronesica* is affected by multiple pest species, with *Aulacapsis yasumatsui*, an introduced cycad specialist armored scale insect, being the most significant threat (Marler and Muniappan 2006, p. 3). A specialist scale predator beetle, *Rhyzobius lophanthae*, was introduced purposefully to treat the *A. yasumatsui* outbreak with some positive results (Marler and Lawrence 2012, pp. 234-238). However, a number of other insects, including cycad blue butterfly (*Chilades pandava*) and a native longhorn beetle that bores cycad stems (*Dihammus marianarum*), also contribute to declining health and mortality in Guam cycad populations (Marler and Muniappan 2006, p. 3; Marler and Lawrence 2012, pp. 238-240).
- Loss and degradation of habitat from development, military training, urbanization, nonnative plants and agriculture.
- Feral pigs and introduced deer are also threats through herbivory and physical damage.
- Stochastic events such as typhoons will continue to degrade forest and the affected forest areas may require several years to regenerate.
- Drought and climate change will exacerbate many of these threats.

Survival and Recovery Needs

In order to recover *Cycas micronesica*, individuals of this species need to be protected on Guam, Rota, Tinian, and Pagan. *C. micronesica* populations should have age structures consisting of seedlings, juveniles, and adult plants. Expanded trials with biocontrol, especially targeting *Aulacapsis yasumatsui*, should be considered to help stabilize the population (Marler and Lawrence 2012; p. 240). In addition, future invasions from other pests must be prevented (Marler and Lawrence 2012; p. 240). Feral pigs and introduced deer are also threats through herbivory and physical damage, further compounding effects from insects (Marler and Lawrence 2012; p. 238); therefore, ungulate control and fencing restoration sites are also crucial steps in managing cycad populations.

Management actions that have occurred in the last five years:

- Since 2007, DON has been maintaining an outplanted population of *C. micronesica* in fenced areas on the island of Tinian, which were selected to represent a broad genetic diversity. These outplantings number about 1,000 mature individuals in each of five fenced exclosures, are maintained to ensure health and survival, and funding for this maintenance is ensured through 2020.

- Five one-acre fenced cycad plots that have been established on AAFB are being maintained as part of a conservation measure from the 2006 ISR Strike biological opinion (USFWS 2006a p. 13, AAFB 2015 p. 8). In addition, monitoring is being conducted within these plots to help inform future management actions (JRM 2015, p. 2-1).

Status of *Tabernaemontana rotensis*

Legal Status

Tabernaemontana rotensis was listed as threatened under the ESA in 2015 (USFWS 2015b, 73 pp.). No critical habitat has been designated for this species. The Service has not completed a recovery plan for *T. rotensis*.

Species Description and Current Known Range

Tabernaemontana rotensis occurs on Guam and Rota, in the forest ecosystem (UOG 2007, p. 6). *T. rotensis* is a small to medium-sized (8-10 m tall) tree in the dogbane family (Apocynaceae). Its leaves are thin, light green, opposite, and 15-30 cm long. Flowers are white, elongate, slender, and branch from the tree. *T. rotensis* produce conspicuous orange fruit that are twinned or single and beaked (UOG 2007, p. 6).

Life History

Tabernaemontana rotensis occurs in forests with crevices of rough limestone (Raulerson and Rinehart 1991, p. 94) and are able to colonize sites that occur in full sun or in deep shade (UOG 2007, p. 16). On Guam, the population structure includes emerging seedlings, young juveniles, and reproductive mature individuals with an immense range in canopy size. Because of the loss of frugivorous bird species on Guam, seed dispersal is very limited and spatial distribution of individuals are clumped within specific areas (UOG 2007; pp. 4, 28). Seedling establishment frequently occurs within the vicinity of mature individuals. These seedlings develop in extreme competition with each other, and many of them become stunted and some die (UOG 2007; pp. 14, 22).

In the absence of typhoons, one study showed that the *Tabernaemontana rotensis* population exhibited an increase in the number of trees flowering in August to October, withthe greatest percentage of trees bearing immature or orange fruit in the following months (UOG 2007, p.23). It also was determined that 40 to 80 percent of trees had a least some flowering occur every month. In typhoon conditions, *T. rotensis* develops a synchronized pulse of flowering about one month after the typhoon. This pulse of flowering leads to a mast seeding event about four months after the typhoon (UOG 2007, p. 29).

The fruit of *T. rotensis* reaches full size approximately 30 to 35 days after flowering. Fruit color changes from bright green to dull green in subsequent months, and a dull orange color break occurs in 50 to 60 days after flowering (UOG 2007, p. 24).

Current Status

In 2007, more than 21,000 *Tabernaemontana rotensis* individuals, comprising of seedlings, juveniles and mature trees, were observed throughout AAFB on Guam. Individuals were located in forest areas: Ritidian Point, Pati Point, HMU, and central and southeast edge of AAFB (JRM 2016, p. 5; UOG 2007, pp. 32-42). *T. rotensis* are present in an area north of route 3A (or northwest of the HMU) on AAFB (AAFB 2014, p. 23). At least five individuals of *T. rotensis* also occur within the GNWR. In addition, 12 saplings of *T. rotensis* have been outplanted on the GNWR (L. Gutierrez, Service, pers. comm. 2016). Multiple *T. rotensis* saplings naturally occur

in the forest on the east or north side of the road, close to the cliffline, which is located outside the GNWR boundary near the old gate (A. Gawel, Service, personal observation. 2016).

In 2014, the CNMI DLNR observed nine individuals on Rota. These individuals were spread across the western, southern, and eastern parts of the island (CNMI DLNR 2014, in litt.). Additionally, there are 30 surviving outplanted individuals, ranging in size from 4 to 23 ft (1.3 to 7 m), spread out across the island (J. Manglona, T. Reyes, R. Ulloa, pers. comm. 2014 cited in CNMI DLNR 2014, in litt.).

Threats
(UOG 2007, p. 28-30; USFWS 2015b, p. 59436)

- Loss and degradation of habitat from agriculture, urban development, military training, nonnative animals and plants, and fires
- Forest fragmentation
- Limited dispersal and recruitment in new habitat.
- Stochastic events - Typhoons will continue to degrade forest and the affected forest areas may require several years to regenerate.
- Climate change will further exacerbate many of the above threats in the future.

Survival and Recovery Needs

In order to recover *Tabernaemontana rotensis*, the remaining individuals of this species need to be protected on Guam and Rota. *T. rotensis* populations should have age structures consisting of seedlings, juveniles, and adult plants. Ungulate and invasive species control should be implemented throughout its range. On Guam, restoring areas with this species' natural dispersers (*e.g.*, native frugivorous birds) would expand the distribution of *T. rotensis* population into new habitat niches, niches that would have likely been naturally occupied by the *T. rotensis* population prior to the loss of seed dispersal on Guam. Outplanting and/or relocation of wild seedlings within protect areas in needed to increase their abundance and distribution on Guam and Rota.

Management actions that have occurred in the last five years:

- From 2014-2015, the Service funded the Guam Plant Extinction Prevention Program (GPEPP) to work on the propagation of *Tabernaemontana rotensis*. GPEPP's mission is to prevent the extinction of Guam's rarest plant species that have fewer than 200 individuals in the wild on Guam. GPEPP works with conservation partners to protect wild populations and reintroduce plants to their natural habitat. The Service is working with GPEPP in efforts to outplant *T. rotensis* within protected areas on Guam.

- GPEPP is building a relational database and geodatabase to connect all plant handling activities. Records from the different GPEPP projects and activities will be stored in this database. The database will house ex situ (wild populations and outplanted population records) and in situ (seed storage, in vitro propagation and Rare Plant Nursery) data.This work is conducted under a U.S. Forest Service grant.

Recommendations for Future Actions:

- Continue monitoring and survey efforts for *Tabernaemontana rotensis*.
- Collect seeds from fruiting trees and develop a nursery of seedlings for outplanting in protected areas throughout its range.
  - *T. rotensis* responds to typhoons with a synchronized flowering pulse (UOG 2007, p. 6). Conservation efforts should ensure harvest of the mast seeding that occurs about four months after the passage of a typhoon (UOG 2007, pp. 22, 29).
- Outplant or relocate wild seedlings to increase their distribution.
  - *T. rotensis* seedlings typically occur in a cluster near the parent tree. The seedlings compete with one another for light and other resources, and not all seedlings survive. Resource managers would benefit from transplanting some of these seedlings prior to their death (UOG 2007, p. 22). This approach also would thin out crowded seedlings and possibly ensure more of them remain alive (UOG 2007, p. 23).
- Eradicate or control ungulates and invasive plants.
- Prevent establishment of introduced invasive species (*e.g.*, insect pests).

Status of *Bulbophyllum guamense*

Legal Status

Bulbophyllum guamense (or siboyas hålum tåno in Chamorro) was listed as threatened under the ESA in 2015 (USFWS 2015, 73 pp.). No critical habitat has been designated for this species. The Service has not completed a recovery plan for *B. guamense*.

Species Description and Current Known Range

Bulbophyllum guamense, an epiphyte in the orchid family (Orchidaceae), occurs in large mat-like formations high on branches of trees. *B. guamense* have leaves that are oblong, elliptic and 10 to 15 cm long (Stone 1970, p. 155), and flowers that are single, fleshy, and greenish-yellow in color (Raulerson and Rinehart 1992, p. 90). The sepals are the most conspicuous part of the flower, while the yellow-green lip with its wine markings is hinged and extremely mobile.

Bulbophyllum guamense is known from widely-distributed occurrences on the southern Mariana Islands of Guam and Rota, in the forest ecosystem (Ames 1914, p. 13; Raulerson and Rinehart 1992, p. 90; Costion and Lorence 2012, pp. 54, 66; Global Biodiversity Information Facility (GBIF) 2012−*Online Herbarium Database*; Zarones et al. 2015a, in litt.). *B. guamense* was recorded historically on Guam from clifflines encircling the island, and on the slopes of Mt. Lamlam and Mt. Almagosa. In 1992, this species was reported to occur in large mat-like formations on trees "all over the island," (Guam) (Raulerson and Rinehart 1992, p. 90). However, *B. guamense* has declined in number and populations on Guam, which represents half its known range. On Rota, *B. guamense* can occur along the Sabana tableland and slopes above 980 ft (300 m) (USFWS 2015, p. 59434).

Life History

Little is known about the life history of *Bulbophyllum guamense*. Members of the genus *Bulbophyllum* are epiphytes (growing on other plants), or have some species are lithophytic (growing on rocks). *B. guamense* is epiphytic and grows on trees within limestone forest type

ecosystems. On AAFB on Guam, this orchid can be observed in limestone forest dominated by the introduced *Vitex*, and in primary limestone forest dominated by *Arctocarpus* and *Ficus* in the lower canopy of closed forest about 10 feet or less above ground. On the Naval Magazine on Guam, this orchid is observed in humid areas in lower elevation, on Areca palms (*Dypsis* sp.) or *Pandanus tetorius* (JRM 2016, pp. 4-9). On Rota, *B. guamense* occurs within the *Hernandia-Eleocarpus* limestone forest ecosystem (USFWS 2015, p. 59434).

Typical to orchids in this genus, *Bulbophyllum guamense* has a carrion-like scent (Raulerson and Rinehart 1992, p. 90). *B. guamense* is almost ever-blooming, as one flower drops, another replaces it until one is pollinated. The ovary then enlarges to form a ribbed capsule about 5-by-1 cm, where the dust-like seeds develop (Raulerson and Rinehart 1992, p. 90). *B. guamense* has a sympodial growth habit which form sequential pseudobulbs (with determinate growth). Research is currently being conducted to determine if we could potentially increase the number of this orchid vegetatively by division within a nursery environment (J. McConnell, UOG, pers comm. 2016).

Current Status

There are approximately 844 individuals on Guam and at least 261 individuals on Rota (USFWS 2015, p. 59434; Joint Region Marianas [JRM] 2016, p. 5). The Naval Magazine contains approximately 753 individuals, which is the majority of known individuals on Guam (JRM 2016, p. 5). Other areas on Guam contain few individuals. Eight *B. guamense* were found during those surveys within the HMU in a limestone forest dominated by non-native *Vitex* (Naval Facilities Marianas 2016, p. 172 as cited in 94th AAMDC 2016). The University of Guam surveys resulted in an observation of one occurrence of *B. guamense* at the Ritidian area (JRM 2016, p. 5).

On Rota, there are at least 261 individuals of *Bulbophyllum guamense* with a population structure consisting of seedlings, juveniles, and flowering adults (Zarones et al. 2015a, in litt). The number of individuals was suggested to be as high as 16,000 individuals on Rota, however this estimate is based on the assumption that *B. guamense* is uniformly distributed across its habitat (Zarones et al. 2015a, in litt).

Bulbophyllum guamense has declined in number of populations and individuals, especially on Guam which represents half of its known range. The remaining individuals are vulnerable to effects of continued habitat loss and other threats as detailed below (USFWS 2015, p. 59434).

Threats (USFWS, p. 59343; see also General Environmental section of this Opinion)

- Loss and degradation of habitat – Development from agriculture, construction, and military training has decreased the recovery habitat for this species. *B. guamense* habitat continues to be degraded by ungulates, nonnative plants, and fires.
- Predation by nonnative slugs.
- Stochastic events - Typhoons will continue to degrade forest and the affected forest areas may require several years to regenerate.
- Climate change will exacerbate many of these threats.

Survival and Recovery Needs

In order to recover and ensure the survival of *Bulbophyllum guamense*, wild populations of this species and its habitat need to be protected and maintained on Guam and Rota. The populations of *B. guamense* should have age structures consisting of seedlings, juveniles, and adult plants. The presence of large, feral ungulate populations on Guam is likely to further degrade remaining forest habitats, thus lowering their value for *B. guamense* recovery. Ungulate control needs to be implemented throughout the range of this species. Similarly, control of nonnative plants and slugs is critical for the conservation of *B. guamense*.

Management actions that have occurred in the last five years:

- For fiscal years 2014-2015, the Service funded the Guam Plant Extinction Prevention Program (GPEPP) to work on the seed germination and propagation of *B. guamense*. GPEPP is working on cultivation of *B. guamense* in their plant nursery.

- GPEPP is building a relational database and geodatabase to connect all plant handling activities. Records from the different GPEPP projects and activities will be stored in this database. The database will house ex situ (wild populations and outplanted population records) and in situ (seed storage, in vitro propagation and Rare Plant Nursery) data. This work is conducted under a U.S. Forest Service grant.

Recommendations for Future Actions:

- Monitor the status of *B. guamense*.
- Determine life history and habitat preferences.
- Identify areas that are needed to be protected for the conservation of *B. guamense*.
- Eradicate or control ungulates within *B. guamense* habitat.
- Determine the best methods in augmenting populations and relocating and/or reintroducing *B. guamense* into protected areas within its historic range.
- Prevent and treat insect infestation on trees.

Status of the *Dendrobium guamense*

Legal Status

Dendrobium guamense was listed under the ESA as threatened in 2015 (USFWS 2015, 73 pp.). No critical habitat has been designated for this species. The Service has not completed a recovery plan for *D. guamense*.

Species Description and Current Known Range

Dendrobium guamense (no common name) is an epiphyte in the orchid family (Orchidaceae). This orchid usually occurs on tree branches in forests in filtered sunlight. Stems are crowded and can be one-meter long. Two small white flowers emerge between two leaves, and are open only one day, appearing as balls on the second day.

Dendrobium guamense occurs in the forest ecosystem on Guam, Rota, Saipan (historically), and Tinian, and recently recorded for the first time on Aguiguan (Ames 1914, p. 14; Raulerson and

Rinehart 1992, p. 98; Raulerson 2006, in litt.; Costion and Lorence 2012, p. 66; Zarones et al. 2015a, in litt.; Zarones et al. 2015b, in litt.). As recently as the 1980s, this species was common in trees on Guam and Rota, with more than 12 occurrences on Guam and 17 occurrences on Rota (Raulerson and Rinehart 1992, p. 98; Consortium Pacific Herbarium 2012a—*Online Herbarium Database,* 5 pp.).

Life History

Little is known about the life history of *Dendrobium guamense.* As an epiphytic orchid, *D. guamense* are supported by trunk and thick lower branches, sometimes in small twigs in the top of the canopy of trees. They cling strongly onto their hosts with a developed root system and use the moisture and organic debris caught in the crevices and bark of the host for nourishment. The humid tropical air is absorbed for additional moisture. In northern Guam, individuals of *D. guamense* were observed mostly on *Ficus prolixa* about 10 to 25 ft high in the canopy (JRM 2016, p. 7). *Dendrobium* species take advantage of the microclimate, which are found on the trunk, lower branches, under the canopy, and can prefer shade or moderate light (Landscape and Garden 2015, in litt). However, *D. guamense* individuals have been observed within forest edges, where there is more than moderate light (A. Gawel, Service, pers. obs. 2016). In the Naval Magazine in southern Guam, *D. guamense* was observed at all elevations along rivers and on ridges and plateaus, and on numerous tree species (JRM 2016, p. 9).

Current Status

There are at least 23 occurrences totaling at least 2,690 individuals distributed on the islands of Guam, Rota, Tinian, and Aguiguan. In 2012, *Dendrobium guamense* was reported present at 4 occurrences totaling fewer than 250 individuals on Guam (Harrington et al. 2012, in litt). During surveys in 2014 to 2015 in DoD areas on Guam, *D. guamense* was observed within habitat surrounded by the Ritidian Ungulate Fence at NWF and over 1,200 were observed in the Naval Magazine (JRM 2016, pp. 4-9). In addition, 29 clumps of approximately 340 individuals are present within the Finegayan area on Guam (DON 2016c). On Rota, at least 15 occurrences of *D. guamense* are present, and a recent survey team reported more than 700 individuals of *D. guamense* on the western third of Rota, represented by seedlings, juveniles, and flowering adults (Harrington et al. 2012, in litt; Zarones et al. 2015a, in litt.). The presence of multiple generations in a healthy population structure indicates that the status of *D. guamense* on Rota is better than previously known. There are two reported occurrences on the island of Tinian, with an unknown number of individuals (Raulerson 2006, in litt.; CPH 2012a—*Online Herbarium Database,* 5 pp.). Zarones et al. (2015b, in litt.) discovered three individuals of *D. guamense* on the island of Aguiguan, a new island record for this species.

The populations of *D. guamense* on Guam, which comprise more than 50 percent of its known range, have declined due to threats predominantly associated with habitat destruction and modification (*i.e.*, development, military training, nonnative plants and animals, fire, typhoons, and climate change) (Harrington et al. 2012, in litt.).

Threats (adapted from USFWS 2015a, pp. 59431, 59453, 59454-5, 59457, 59459, and 59467):

- Loss or Degradation of Habitat
  - Incremental habitat loss due to wild fire, urbanization, and agricultural development is increasingly threatening the availability of habitat.

  - The ongoing and proposed expansion plans of DoD training and operations on Guam are threatening the remaining *D. guamense* habitat and potential future conservation efforts from the activities associated with the expansion.
  - As numbers of cattle and ranchers increase on Tinian, there may be a greater risk of cattle potentially escaping and becoming feral. Both feral and domestic cattle can drastically alter the landscape (Wiles et al. 1990, pp. 176–177), and depending on the location and amount of land designated as pasture land for domestic cattle, negative impacts to the forest ecosystem may be observed in the future, minimizing the available habitat.
  - The presence of nonnative plants and other nonnative ungulates (pigs, goats, and water buffalo), and Philippine deer, is likely to further degrade remaining forest habitats, thus impeding their ability to survive.

- Predation
  - Nonnative slugs have been observed to cause mechanical damage to plants and destruction of plant parts (branches, fruits, and seeds), including orchids, and are considered.

- Stochastic Events
  - Typhoons will continue to degrade forest and the affected forest areas may require several years to recover.
  - On a global scale, sea level is rising as a result of thermal expansion of warming ocean water; the melting of ice sheets, glaciers, and ice caps; and the addition of water from terrestrial systems (Church et al. 2013). Individuals that occur close to the coast in the adjacent forest ecosystem at or near sea-level and may be negatively impacted by sea-level rise and coastal inundation due to climate change.

- Climate Change
  - We anticipate the effects of climate change will further exacerbate many of the above threats in the future (USFWS 2015b, pp. 59435-6)

Survival and Recovery Needs

In order to recover *Dendrobium guamense*, individuals of this species in the wild and their habitat need to be protected on Guam, Rota, Tinian, and Aguiguan. *D. guamense* populations should have age structures consisting of seedlings, juveniles, and adult plants. The presence of large, feral ungulate populations on islands is likely to further degrade remaining forest habitats, thus lowering their value for *D. guamense* recovery. Ungulate control needs to be implemented throughout the range of this species. Similarly, control of nonnative plants and slugs is critical for their recovery.

Management actions that have occurred in the last five years:

- From fiscal years 2014-2015, the Service funded GPEPP to work on the propagation of *D. guamense*. GPEPP's mission is to prevent the extinction of Guam's rarest plant species that have fewer than 200 individuals in the wild on Guam. GPEPP works with conservation partners to protect wild populations and reintroduce plants to their natural habitat. The Service is working with GPEPP in efforts to outplant *D. guamense* within protected areas on Guam.

- GPEPP is building a relational database and geodatabase to connect all plant handling activities. Records from the different GPEPP projects and activities will be stored in this database. The database will house ex situ (wild populations and outplanted population records) and in situ (seed storage, in vitro propagation and Rare Plant Nursery) data. This work is conducted under a U.S. Forest Service grant.

- A conservation project on Rota, administered through the Water and Environmental Research Institute of the Western Pacific at the University of Guam, is aimed to analyze the island's hydrology, with the ultimate goal of protection of the Sabana Watershed and Talakhaya Springs (Keel et al. 2007, pp. 5, 22–23). Erosion control, revegetation, and water source preservation conducted as part of this project may provide protection to *D. guamense* (USFWS 2015b, p. 59460).

Recommendations for Future Actions:

- Monitor the status of *D. guamense*.
- Determine life history and habitat preferences.
- Identify areas that are needed to be protected for the conservation of *D. guamense*.
- Eradicate or control ungulates within *D. guamense* habitat.
- Determine the best methods in augmenting populations and relocating and/or reintroducing *D. guamense* into protected areas within its historic range.
- Prevent and treat insect infestation on trees.

Status of *Tuberolabium guamense*

Legal Status

Tuberolabium guamense (no common name) was listed under the ESA as threatened in 2015 (USFWS 2015, 73 pp.). No critical habitat has been designated for this species. The Service has not completed a recovery plan for *T. guamense*.

Species Description and Known Range

Tuberolabium guamense is an epiphytic orchid with roots that elevate the leaves and flowers away from the tree trunk. Leaves are leathery, oblong, about 13 cm long and 1.5 cm wide. Small white flowers are on a rachis about 3.5 cm long (Raulerson and Rinehart 1992, p. 127). *T. guamense* occurs in forest ecosystems on Guam and Rota (Raulerson and Rinehart 1992, p. 127; USFWS 2015), with a few scattered historical occurrences on Tinian and Aguiguan (CPH 2012b - *Online Herbarium Database*; USFWS 2015b).

There is limited information on the distribution of *Tuberolabium guamense*. However, most orchids are narrowly distributed in specific habitats (Lozano et al. 1996, Cribb et al. 2003, Zang et al. 2015). Accordingly, *T. guamense* are not distributed uniformly throughout the forests; and where they occur, they are present in clusters. For example, at least 145 individuals were located on four trees adjacent to one another in the forest within the Finegayan area on Guam (USFWS 2016).

Life History

Similar to other epiphytic orchids, *Tuberolabium guamense* grows slowly and requires specific microclimates, which are found on the trunk, lower branches, and under the forest canopy. *T. guamense* clings onto their host trees with a strong developed root system and uses the moisture in the air and organic debris caught in the crevices and bark of the host for nourishment.

Orchids are known to have long lifespans (Dressler 1993, p. 226) and seedlings can require 2 to 10 years or more, depending on the species, before they are large enough to flower, with most common orchid species taking 2 or 3 years. Epiphytic orchids may need 30 years to reach maturity (Zotz 1995). The age of maturity and the lifespan of *Tuberolabium guamense* are unknown. However, McConnell (2016) indicated *T. guamense* grows slowly and is a long-lived plant. In addition, *T. guamense* exhibits a monopodial growth habit in which the stem may continue to grow indefinitely (McConnell 2016).

There is limited information on the life history and habitat preferences of *Tuberolabium guamense*. However, observations of *T. guamense* indicated this species is associated with *Taeniophyllum mariannense* (worm orchid) and moss on host trees. *T. guamense* is generally located in high humid areas that are protected from wind within the forest (USFWS 2016). On Guam, biologists have observed *T. guamense* present in areas with low to moderate sunlight within the forest, and no individuals were observed in moderately shaded areas (USFWS 2016). *Tuberolabium guamense* also was observed growing on bark of *Vitex parvifloara* at a height of 3 to 20 ft and some individuals were observed on *Guamia mariannae* (JRM 2016, p. 6). *T. guamense* occurs in forest habitat adjacent to rivers on Guam, mostly on *Areca catechu* and *Cocos nucifera*. They were occasional present on *Vitex* and *Pandanus* (JRM 2016, p. 8).

On Rota, the *Tuberolabium guamense* population occurs within a specialized niche of limestone forest within the Sabana region, a raised plateau unique in the Marianas (USFWS 2015b). Forests located within the Sabana are often shrouded in clouds and mist, and some areas include healthy growths of epiphytes (USDA 1989, p. 6). Zarones et al. (2015a) indicated that *T. guamense* occurs in native canopy trees, with the majority of individuals found on *Hernandia labyrinthica*, *Premna obtusifolia*, and *Elaeocarpus joga* (Zarones *et al.* 2015a, in litt.).

Current Status of Tuberolabium guamense

Tuberolabium guamense is present in discrete, restricted populations on the islands of Rota and Guam. In 1992, Raulerson and Rinehart (p. 87) stated that although *T. guamense* may appear abundant on the limestone ridges, the habitats are limited and in reality these orchids are very rare on Rota and Guam. For example, the Rota *T. guamense* population occurs in clusters within limestone forest within a specialized niche in the Sabana region, and the Guam *T. guamense* population occurs in clusters at only four known locations with one site harboring over 90 percent of the known population rangewide (DON 2016, Table 1; JRM 2016 p. 5). *T. guamense* populations are vulnerable to ongoing threats posed by the continued habitat loss and destruction from agricultuare, urban development, nonnative animals and plants, fires, typhoons, and herbivory by slugs. We anticipate the effects of climate change will further exacerbate many of these threats in the future (USFWS 2015b, p. 59424).

Table 1. Known *Tuberolabium guamense* Populations on Guam and Rota.

Known Populations	Number of *T. guamense* [a]	Landownership	Conservation Status
HMU, Guam	251	DoD	None
Ritidian Point, Guam	105	DoD	None
Naval Magazine, Guam	188	DoD	None
Finegayan, Guam	6,576	DoD	None
Sabana, Rota[a]	239	CNMI	Conservation Area

HMU – Habitat Management Unit, DoD – Department of Defense, CNMI – U.S. Commonwealth of the Northern Mariana Islands [a] Number of *T. guamense* includes seedlings, juveniles, and flowering adults.

Currently, the Sabana Region is the only area where *Tuberolabium guamense* is present that has a formal conservation area designation. The Sabana Region, a high plateau area in the southwestern portion of Rota, was established as a protected area in 1994 under Rota Local Law 9-1. The HMU on AAFB was developed as a conservation measure under the 2006, informal consultation on the Beddown of Training and Support Initiative at the Northwest Field (USFWS 2006c, p. 2), and currently serves as an experimental site for brown treesnake research and control.

Threats (adapted from USFWS 2015a, pp. 59431, 59452, 59454-5, 59457, 59459, and 59467):

- Loss or Degradation of Habitat
  - Incremental habitat loss due to wild fire, urbanization, and agricultural development is increasingly threatening the availability of habitat.
  - The ongoing and proposed expansion plans of DoD training and operations on Guam are threatening the remaining *T. guamense* habitat and potential future conservation efforts from the activities associated with the expansion.
  - The presence of nonnative plants and nonnative ungulates (pigs, goats, and water buffalo), and Philippine deer that degrade forest habitats.
- Predation
  - Nonnative slugs have been observed to cause mechanical damage to plants and destruction of plant parts (branches, fruits, and seeds), including orchids, and are considered a threat.
- Stochastic Events
  - Typhoons will continue to degrade forest and the affected forest areas may require several years to propagate. In addition, the presence of nonnative vertebrates can exacerbate the impact of storms by impeding regeneration and seral development.
- Climate Change
  - We anticipate the effects of climate change will further exacerbate many of the above threats in the future (USFWS 2015b, pp. 59435-6).

Survival and Recovery Needs

Tuberolabium guamense does not occur uniformly within forest habitat. It grows in more humid areas where moss is present on trees and other epiphytic growth including ferns and other native orchids occur. Local site conditions may have a large impact on population dynamics of orchid species, and differences in populations may be due to variables such as seed germination or the availability of suitable fungi to promote seed germination (Perkins and McGee 1995, pp. 565–

575; Jersakova and Malinova 2007, pp. 237-241; Jacquemyn 2010, pp. 119-129). Therefore, it is important to conserve habitats in which the remaining large population of rare orchids occurs, in order to save them from extirpation (Cozzolino et al. 2003, pp. 1684-1686). Furthermore, habitat size is important for orchids because larger habitats will support higher numbers of orchids, and will likely provide greater opportunity for orchids to survive changing environmental conditions by providing orchids suitable areas to colonize if current habitat becomes unsuitable. Larger habitats are also more likely to support greater levels of natural disturbances, and thus more patch disturbance for orchid seedling establishment and potential for orchid colonization. The Finegayan area contains the largest and most robust population of *T. guamense*; the majority (over 90 percent) of the known population on Guam occurs as clusters in this area. Therefore, protection and management of this area is essential to the conservation of this species on Guam.

Because epiphytic orchids are restricted to microclimates and thus sensitive to changes in climate conditions, as well as often slow growing, they are more vulnerable to disturbance than other plants (Hietz 1999). *Tuberolabium guamense* is geographically restricted and requires a specific microclimate to survive. Thus, *T. guamense* grows and reproduces best where they grow naturally in the wild (Raulerson and Rinehart 1992, p.87). The likelihood of this species surviving and recovering is dependent on maintaining the microclimate requirements of *T. guamense* where they occur in forests on Guam and Rota.

As discussed above, *Tuberolabium guamense* populations are geographically restricted, and are subject to further decline due to continued habitat loss and destruction from agriculture, urban development, nonnative animals and plants, and typhoons. Because *T. guamense* grows slowly and may need several years to mature, current population growth rates may not be sufficient to maintain a stable population. In general, species with slow growth rates are less able to compensate for increased mortality (Huston 2004, p. 169). In addition, epiphytes depend on host plants or trees and any conversion or loss of their host will result in a complete loss of epiphytes in the affected area (Hietz 1999, p. 2). Therefore, given the current status of *T. guamense* and their specific habitat requirements and life history, protecting and maintaining all five known populations are essential for the survival and recovery of this species.

More specifically, the conservation needs of the *T. guamense* are as follows:

1. Protect, maintain, and enhance the habitat of the five known *T. guamense* populations. Because *T. guamense* is restricted to microclimates and thus sensitive to changes in climate conditions, as well as often slow growing, they are more vulnerable to disturbance. Restoration and management activities should focus on reducing threats to *T. guamense* populations to insure their long-term persistence and viability. Habitat should be managed to support stable or increasing populations of the orchid.

2. Restore populations of *T. guamense* (i.e. HMU, Naval Magazine, Ritidian, and Sabana) to higher numbers of plants capable of withstanding random genetic or demographic events or environmental catastrophes that might otherwise cause population extirpation.

3. Research should be conducted on methods for reestablishing and augmenting *T. guamense* populations within its historic range. In order to build resiliency, additional populations are needed that are protected and managed to insure survival and recovery of the species.

4. The occurrence of large, feral ungulate populations in the Mariana Islands further degrades the remaining forest habitats, thus lowering their value for *T. guamense* recovery. Ungulate control

needs to be implemented throughout the range of this species. Similarly, control of nonnative plants and slugs is critical for their recovery.

Management actions that have occurred in the last five years:

- For fiscal years 2014-2015, the Service funded the Guam Plant Extinction Prevention Program (GPEPP) to work on the seed germination and propagation of *T. guamense*. GPEPP is working on cultivation of *T. guamense* in their plant nursery.

- GPEPP is building a relational database and geodatabase to connect all plant handling activities. Records from the different GPEPP projects and activities will be stored in this database. The database will house ex situ (wild populations) and in situ (seed storage, in vitro propagation and Rare Plant Nursery) data. This work is conducted under a U.S. Forest Service grant.

Future Conservation Actions Needed for *Tuberolabium guamense*:

- Monitor the status of *T. guamense*.
- Determine life history and habitat requirements and preferences.
- Identify core areas critical to the conservation and long-term survival and recovery of *T. guamense* and institute appropriate measures to protect and conserve those habitats.
- Eradicate or control ungulates within *T. guamense* habitat.
- Determine the best methods in augmenting populations and relocating and/or reintroducing *T. guamense* into protected areas within its historic range.
- Prevent and treat insect and other invertebrate infestation on host trees.

Mitigation framework

In consideration of the on-going and increased habitat loss and degradation on Guam (as detailed in the General Environmental Baseline section) the Service has endeavored to finalize the draft Mitigation Framework (USFWS 2014e), including the mitigation ratio for habitat loss, to address future habitat conservation needs for the Guam Micronesian kingfisher (USFWS 2015c). As land management actions are proposed that will affect habitat needed for the recovery and survival of the kingfisher, it will be necessary to offset these effects by assuring that durable habitat will be protected and available for species reintroduction. This can be accomplished by ensuring that any habitat that is lost is offset with permanent habitat conservation at rates that ensure an adequate amount of habitat is needed to support the survival and recovery of the kingfisher on Guam.

The mitigation ratio took into account kingfisher habitat that was already protected in northern and southern Guam. For northern Guam, approximately 571 acres of kingfisher habitat was protected before the Memorandum of Agreement with DoN was signed. There is no kingfisher habitat protected in southern Guam. Kingfisher habitat should be protected to the maximum extent possible until restoration and management practices for kingfisher habitat are proven to work.

The Mitigation Framework provides guidance to ensuring that adequate amounts of the habitat will be available for species reintroduction in the future. We have recommended to the DON that they should assure that any habitat that is lost as a result of proposed projects is offset with permanent habitat conservation at a rate that ensures the minimum amount of habitat needed to

support kingfisher conservation will ultimately be available to support the recovery and survival of the species in the wild on Guam.

EFFECTS OF THE ACTION

The vegetation clearing and construction for the placement of the THAAD and CDZ, supporting infrastructure, operation of the THAAD (including EMR), movement of personnel, avoidance and minimization measures, and conservation measures are considered in this effects analysis. The CDZ training activities are analyzed and considered in a previous biological opinion (2001-F-0001).

Habitat loss and degradation

The proposed action has resulted (and will result) in habitat loss, degradation, and fragmentation (including edge effects) from clearing, as well as light and noise disturbance. The habitat loss, degradation, and fragmentation will decrease the amount of suitable habitat for recovery of listed species on Guam. The loss of limestone forest and listed species habitats increases time to recovery as a result of small acreages of remaining native forested habitat on Guam, and threatens future recovery of listed species on Guam. Given the small amount of habitat left on Guam, off-setting measures to protect remaining limestone forest and listed species habitats are needed.

Habitat suitable for the survival and recovery of the Guam Micronesian kingfisher, Guam rail, Mariana crow, and Mariana fruit bat has been delineated on Guam (Amidon 2012, in litt.). Because *Cycas micronesica* has been considered one of the dominant trees within the forests on Guam, we used the number of acres for the kingfisher and bat, to estimate the amount of habitat loss for *C. micronesica*. More information on *Tabernaemontana rotensis* and the listed orchids is needed to estimate the amount of habitat loss for these species.

Table 2. Amount of recovery habitat affected by proposed action.

Species	**Recovery Habitat Available in Guam (acres)**	**Cleared/Disturbed for THAAD/CDZ Action (acres)**	**Recovery Habitat Remaining After Action (acres)**	**Proposed Conservation Area**
Mariana Fruit Bat	26,075	87.1	25,987.9	334.7
Guam Micronesian Kingfisher	26,977	85.8	26,891.2	334.7
Mariana Crow	23,587	85.2	23,501.8	334.7
Guam Rail	48,422	140.6	48,281.4	334.7*
Cycas micronesica	26,977	85.8	26,889.9	334.7

*Rails utilize edge habitat and ecotones, and therefore, are less likely to benefit from dense forest areas that other listed species would utilize.

Effects to the Mariana fruit bat

A total of 87.1 acres of bat recovery habitat will be disturbed (cleared or physically modified) for this action. Of the 26,075 acres of recovery habitat available for bats in Guam, this constitutes a loss of less than 0.4%. Although most components of this action are located in previously disturbed areas, placement and operation of the THAAD and shift in CDZ activities will further

degrade areas of Northwest Field that were either potential habitat or developed areas that could be used as corridors or pathways to roosting and foraging habitat at Ritidian and Anao. Based on calculations made for fruit bat habitat loss from the Marine relocation and military build-up consultation (USFWS 2015a), 100 acres of fruit bat habitat could potentially contain 96 bats. Therefore, the loss of 87.1 acres for this project decreases the carrying capacity of remaining fruit bat habitat in Guam by approximately 84 bats, and results in the permanent loss of 87.1 acres of potential breeding, foraging, and sheltering habitat

The Mariana fruit bat has high energetic demands associated with flight and year-round breeding, and as such depends on a steady and ample supply of fruiting and flowering plants that are supplied patchily through space and time (Wiles and Fujita 1992, pp. 26-31; USFWS 2009a p. vi). To meet requirements for breeding, feeding, and sheltering, a self-sustaining population of Mariana fruit bats will rely on threat-managed, native limestone forest habitat containing diverse food resources that are available throughout the year. Because of this patchy distribution through space and time, extensive amounts of habitat need to be available in order to meet recovery needs.

Re-establishing and maintaining a widely-distributed, robust metapopulation of fanihi in the Mariana Islands is critical to long-term persistence of the species (USFWS in review, p. 45). Distribution in both the northern and southern islands of the Marianas is essential (USFWS in review, p. 45), and delisting criteria calls for stable or increasing populations on three of the five southern Marianas Islands (Saipan, Rota, Tinian, Aguiguan, and Guam) (USFWS 2009, p. 37-39). Much of the forests in Saipan and Tinian have been degraded historically, and Aguiguan is very small in size. Guam is the largest island in the Mariana Island chain with the largest potential habitat for bats, and therefore, the habitats on Guam are essential to recovery because they can provide enough habitat containing diverse food resources that are available throughout the year . That being said, Guam's forests continue to be subject to loss and degradation, and the rate of habitat conservation does not keep sufficient pace with the proposed rate of habitat loss (USFWS 2014e p. 2). Therefore, even a habitat loss of 87.1 acres presents adverse effects to the Mariana fruit bat because of the importance of habitat in Guam to recovery of the species, and because this important habitat continues to decline island-wide. However, because the habitat loss is still relatively small, the loss of this habitat due to the proposed action is not likely to result in jeopardy to the species.

The operation of the THAAD involves use of EMR, which has the capability of negatively impacting animals such as birds and bats when exposed for extended periods of time to the radar beam. However, the chances of adverse effects to bats are extremely low due to the following factors:

- All land within 2,000 feet of the radar system has been cleared of trees. Since bats tend to roost and forage in forested areas, crossing open areas only to get between areas of foraging and roosting, it is unlikely that any bats in the area would remain within a radar beam for long enough for any dangerous levels of exposure.
- Bats in forested areas near the radar beam would not likely be exposed because the lowest elevation of the radar beam is at least 170 ft. above ground level at the nearest forest edge.
- The THAAD system most often operates in search/surveillance mode, and bats flying past or towards the radar system would be exposed to EMR for a very short duration (less

than 0.2 seconds), which would not result in adverse physical, physiological, social, or ecological, consequences.

- While tracking a target, a cross section of the radar beam at 350 meters away from the device is an ellipse that measures 19.6 meters vertically and 9.8 meters horizontally, but is narrower closer to the radar, at heights that fruit bats would be more likely to be flying (Hubbs 2016, in litt.). The chances that a bat will move in the same direction and at the same speed as the constant beam while tracking a target, and therefore be exposed to potentially damaging levels of radiation, are extremely small.
- Because of the human activity at the location of the THAAD stationing, namely noise, human smells, man-made structures, vehicles, and lights, it is unlikely that bats will fly over these areas, as bats in the Marianas are known to avoid human-caused stressors (see Status of the Species above).

The Department of Defense proposes to set aside 334.7 acres of habitat for conservation (described above). This will help mitigate the loss of about 87 acres of recovery habitat for bats.

In conclusion, this action, although presenting adverse effects to bats through habitat loss, is not likely to result in jeopardy of this species. In addition, the commitment to conserve 334.7 acres of habitat for restoration and conservation will help to offset adverse effects. At the time of this consultation, limited information was available about the effects of EMR on wildlife, especially with regards to repeated exposure. If new information becomes available that could potentially contradict these results, this analysis will be revisited.

Effects to the Guam Micronesian kingfisher

A total of 85.8 acres of kingfisher recovery habitat will be disturbed (cleared or physically modified) permanently for this action. This constitutes less than 0.4% of the specie's remaining habitat in Guam. Because the kingfisher does not currently exist in the wild, no direct adverse impacts are expected except through habitat loss and disturbance. The Department of Defense proposes to set aside 334.7 acres of habitat for conservation (described above). This will help mitigate the loss of 85.8 acres. In the event that extirpated birds are reintroduced to northern Guam, this analysis will be revisited.

Maintaining an adequate amount of habitat for recovery is of utmost concern for the Guam Micronesian kingfisher. The kingfisher recovery plan sets a goal of 1,000 adult kingfishers in Guam – 500 in northern and 500 in southern Guam – for delisting (USFWS 2008a). Mating pairs of kingfishers are estimated to require approximately 20 acres of habitat each (Kesler and Haig 2007a, pp. 386-387). This would require about 11,500 acres each in northern and southern Guam. About 71% of the kingfisher's remaining recovery habitat in northern Guam is located on DoD property. With the current rate of development both on and off DoD properties, the degraded state of much of this habitat due to lack of management and the presence of ungulates, and the continued presence of the brown treesnake throughout Guam, the recovery prospects for this island-endemic bird is tenuous. This project will result in the loss of 85.8 acres of habitat, which could potentially support 4 mating pairs of kingfishers. The recovery habitat remaining in northern Guam amounts to approximately 15,000 acres, or only about 3,500 acres left above recovery thresholds available before recovery is compromised (USFWS 2014e, pp. 1-6). The habitat loss from the proposed action is a small fraction of the total habitat remaining for kingfisher recovery on Guam. However, because of the tenuous situation for recovery described above, the Service continues to closely track loss of habitat and encourage project proponents to

ensure conservation of habitat for the kingfisher. Because so little habitat remains above the threshold, even small losses can result in adverse effects to the recovery of kingfishers.

In conclusion, this action, although presenting adverse effects to kingfishers through habitat loss and degradation, is not likely to result in jeopardy of this species. In addition, the commitment to conserve 334.7 acres of habitat for restoration and conservation will help to offset adverse effects. At the time of this consultation, limited information was available about the effects of EMR on wildlife, especially with regards to repeated exposure. If new information becomes available that could potentially contradict these results, this analysis will be revisited. In addition, in the event that extirpated kingfishers are reintroduced to northern Guam, this analysis will be revisited.

Effects to the Mariana crow

A total of 85.2 acres of Mariana crow recovery habitat will be disturbed (cleared or physically modified) permanently for this action. This constitutes less than 0.4% of the remaining habitat for this species in the wild in Guam. Because the crow does not currently exist in the wild in Guam, no direct adverse impacts are expected except through habitat loss and disturbance. The Department of Defense proposes to set aside 334.7 acres of habitat for conservation (described above) to mitigate the loss of 85.2 acres.

The Mariana crow recovery plan sets a goal of three populations, one in Rota, one in northern Guam, and one in southern Guam, each with 75 mating pairs (USFWS 2005a, p. v). However, as mentioned in the Status of the Species above, new information and analyses recommend 100 mating pairs in each of these populations are more likely to maintain sustainable populations (Amidon 2012, unpubl. data). There are currently 13,962 acres of potential crow habitat in northern Guam (USFWS 2015a p. 125). However, to achieve recovery goals, a minimum of approximately 5,500 acres of recovery habitat needs to be maintained in northern Guam. With the current rate of development both on and off DoD properties, the degraded state of much of this habitat due to lack of management and the presence of ungulates, and the continued presence of the brown treesnake throughout Guam, the recovery prospects for this island-endemic bird is tenuous. Unlike the kingfisher, however, the crow still exists in the wild on the island of Rota, and while recovery criteria call for a small number (100 breeding pairs rather than 500 for kingfisher), each crow pair requires a larger number of habitat for territory. Therefore, while habitat is certainly a limiting factor in crow recovery due to its limited native range and relatively large territory requirements, the loss of crow habitat due to this action will cause limited adverse effects, especially with the commitment to conserve and restore habitat to mitigate this loss.

In conclusion, this action, although presenting adverse effects to crows through habitat loss and degradation, is not likely to result in jeopardy of this species. In addition, the commitment to conserve 334.7 acres of habitat for restoration and conservation will help to offset adverse effects. At the time of this consultation, limited information was available about the effects of EMR on wildlife, especially with regards to repeated exposure. If new information becomes available that could potentially contradict these results, this analysis will be revisited. In addition, in the event that crows are reintroduced to northern Guam, this analysis will be revisited.

Effects to the Guam rail

A total of 140.6 acres of rail recovery habitat will be disturbed (cleared or physically modified) for this action. This constitutes less than 0.3% of this species' remaining habitat in Guam. Because rails are extirpated in the wild in Guam, no direct adverse impacts are expected to individual birds except through habitat loss and disturbance.

While the Guam rail is also a single island endemic, because of its ability to use edge and disturbed habitat as well as savannah and forests, the rail's recovery prospects in Guam are less limited by habitat availability. There are approximately 24,698 acres and 24,886 acres of recovery habitat in northern and southern Guam, respectively, for the Guam rail (USFWS 2015a, p. 128). This action will result in the loss of 140.6 acres of rail recovery habitat. Although a higher number of acreage lost than for other avian species, this is a smaller proportion of the total recovery habitat remaining for this species. Therefore, while the rail is still absent in the wild in Guam, and the presence of the snake and continued degradation or development of recovery habitat continues, the adverse effects to recovery habitat from this project are small in scale and unlikely to hinder the recovery prospects for this species.

In conclusion, the this action, although presenting adverse effects to rails through habitat loss, is not likely to result in jeopardy of this species. The Army, with collaboration from the Navy and Air Force, proposes to set aside 334.7 acres of habitat for conservation (described above). While this will be of help mainly to crows, kingfishers, bats, and listed plants, restoration activities that help to control or exclude brown treesnakes in these areas will have benefits to rails. Since rails are flightless, it is unlikely any new information about the effects of EMR will pertain to rails. However, in the event that extirpated rails are reintroduced to northern Guam, the Service and project proponent may decide to revisit this analysis.

Effects to *Cycas micronesica* and *Tabernaemontana rotensis*

Recovery habitat layers for the two listed plants *Cycas micronesica* and *Tabernaemontana rotensis* have yet to be developed. However, based on current knowledge of *C. micronesica*, it is evenly distributed through most types of forest habitat in Guam, similar to habitat suitable for birds, bats, and kingfishers. Therefore, it is reasonable to assume that habitat lost for these species would be habitat that could be suitable for cycads. We chose to use kingfisher numbers because of the nature of the habitat utilized by this species – limestone forest, but with potential for use of secondary growth such as coconut plantations. Since cycads occur in multiple types of forest habitat, even in secondary growth and previously disturbed areas, we assume the number of recovery habitat available in Guam, as well as the amount of recovery habitat to be cleared and set aside for restoration, will be similar. We anticipate that cycads, being more widely and regularly distributed in forests of northern Guam, are more likely to be found in larger numbers. However, over 20 acres be cleared consists of secondary forests with heavy monotypic stands of *Casuarina equisetifolia*, with about 42 acres consisting of mixed limestone forest-plateau/secondary (94th AAMDC 2016). The proposed clearing for a fiber-optics line will be an additional 2.4 acres of forest or perennial scrub. Based on the estimated density of approximately 1.5 cycads per acre on AAFB (based on Marler 2014), the proposed action has the potential to clear or disturb up to 110 cycads because of clearing for the CDZ (72.6 acres of forest or scrub cleared). This number may be lower because the flexibility allowed for placement of the fiber-optics line.

Tabernaemontana rotensis, in contrast, is patchily distributed in limestone forest areas of northern Guam. In addition, and ecological information about this species is still very limited. However, *T. rotensis* has been recorded near the action area, as well as in similar habitat types in northern Guam (UOG 2007, p. 9; 94th AAMDC 2016, p. 1-25). When it occurs, it tends to occur in clusters or high-density clumps (UOG 2007, p. 9, 14), with very few exceptions of 1-2 individuals more than 100m from other *T. rotensis* individuals. Because the action area, while not thoroughly surveyed, has been observed on multiple occasions by biologists and botanists, we believe that since this species occurs in high-density clumps, it will be unlikely to find any high-density clusters of this species within the action area of this project. Therefore, we anticipate no more than five individuals will be impacted by the proposed action. If individuals are found, they can either be avoided, or they will be occurrences that are not a part of a large cluster.

A large cluster of *T. rotensis* occurs within and near the proposed conservation mitigation area (the largest contiguous portion of the proposed conservation area, 330.1 acres) on the eastern side of AAFB. Therefore, we anticipate the conservation area to be particularly beneficial to *T. rotensis* by long-term protection from development and human disturbance, and by conservation actions, especially ungulate control and exclusion. Cycads also occur within the proposed conservation areas, and we anticipate that conservation actions such as ungulate control and exclusion may prove beneficial to cycads in the area. However, we also recommend research and pest control for cycads since based on the onslaught of threats to this species, especially from arthropod pests, ungulates are only one of many factors contributing to their decline (USFWS 2015b, 73 pp.).

Effects to Listed Orchids

In the revised Biological Analysis (94th AAMDC 2016), the Army indicated that it was possible that several individuals of the following species, three orchid species and one tree species, not analyzed above, may have been found in the footprint of the emergency placement of the THAAD:

Bulbophyllum guamense
Dendrobium guamense
Tuberolabium guamense

At the time of the emergency placement, these species were not listed, and there is no way to confirm their presence in the project footprint that has already been cleared. Based on the description of the areas yet to be cleared, we believe it is unlikely but possible that a small number of these orchids occur and therefore will be impacted in the proposed project footprint.

Effects to *Bulbophyllum guamense*

B. guamense, like many forest orchids in the Marianas, occurs in forested areas with high humidity. While the Guam Plant Extinction Prevention Program (GPEPP) documented two individuals of *B. guamense* in the Habitat Management Unit (HMU) in AAFB in northern Guam, they documented much higher numbers in the river valleys of southern Guam – 62 along the Atmasogu River and 214 along the Maulap River, which were surveyed within the Naval Munitions Storage installation (JRM 2016 p. 5). River valleys, because of their topography and more consistent presence of water, retain more moisture and experience less air movement,

creating ideal conditions for *B. guamense*. Most of the vegetation types that are planned for clearing for this project are previously disturbed areas dominated by *Casuarina equisetifolia* and are located on the edges of roads or runways with little to no understory, allowing for more air movement, and therefore, dryer conditions. The proposed placement of the underground fiber-optic cable largely follows along roads, runways, or fenclines that have already been cleared or disturbed. However, a long, narrow, rectangular area, about 30 acres in size, northwest of the North Runway is planned for clearing for the Cargo Drop Zone activities (Figure 3). This rectangular area contains some patches of dense native canopy including large *Tristiropsis obtusangula* trees (Figure 5) and more rugged karst substrate distinct from the *C. equisetifolia* strands alongside the runways at Northwest Field. Other native trees such as *Psychotria mariana*, *Aglaia mariannensis*, *Hibiscus tiliaceus*, *Pandanus* sp., and *Ficus prolixa* were recorded here, as well as non-native trees such as *Vitex parviflora* (A. Gawel, USFWS, 2016 pers. obs.). *B. guamense*, while not observed at the time these species were recorded, has been recorded at other sites on both native trees such as *Ficus prolixa* and on the invasive tree *Vitex parviflora*, which occurs in high numbers. Therefore, while the exact number of *B. guamense* that would be disturbed by this action is unknown, we do not anticipate more than 5 individuals would be impacted by this action. It is also possible that no individuals will be impacted.

Effects to *Tuberolabium guamense*

Tuberolabium guamense is also an epiphytic orchid that can be found in multiple forest types. While patchily distributed across its range, it can occur in dense clusters where it is found, as evidenced by the presence of over 5,000 individuals within a 1,213-acre area of Finegayan in northern Guam (USFWS 2015b, p. 16; DON 2016, 11 pp.). The majority of the Finegayan area is mixed secondary limestone forest dominated by *Vitex parviflora*, *Hibiscus tiliaceus*, *Pandanus dubius*, *Pandanus tectorius*, *Guamia mariannae*, *Morinda citrifolia*, and *Triphasia trifolia* (DON 2016, p. 1). This habitat is similar in species composition to the 30-acre area of the Cargo Drop Zone (CDZ) clearing described above for the effects to *Bulbophyllum guamense*, which also contains some *Eugenia* forest (Figure 4) However, the Finegayan area is comprised of a larger area of contiguous forest while the area to be cleared for the CDZ occurs in a narrow strip of forest fragment abutting roads and helicopter landing pads. The pockets of high density of *T. guamense* within the Finegayan area were marked by limited air movement and high humidity (USFWS 2016, Field Notes), which contrasts with the 30-acre area of the proposed CDZ clearing, which has more air movement,

While clumped and not evenly distributed, the density of *T. guamense* in the 1,213-acre area of Finegayan amounts to approximately 4 orchids per acre. Based on the vegetation characteristics described above, and the limited knowledge we have about *T. guamense* habitat and occurrences, we anticipate that this action may adversely affect up to 120 *T. guamense* individuals. However, it is possible that fewer or even no orchids will be present because of the exposure of more of the project footprint to air movement, being adjacent to large runways and helicopter-landing pads.

Effects to *Dendrobium guamense*

In contrast to the orchid species analyzed above, *Dendrobium guamense* occurs across multiple habitat types, including at all elevations along rivers and on ridges and plateaus, co-occuring with other species of orchids, but also occurring on ridges, plateaus, on trees that are within or near savannah, and on trees on forest edges (JRM 2016, p. 9; A. Gawel, Service, pers. obs. 2016). They are epiphytes on multiple species. While they occur across a variety of habitat types,

recent surveys suggest that they are more abundant in the forests of southern Guam. Surveys done on DON lands found higher numbers in the river valleys of southern Guam as compared to limestone forest areas adjacent to the action area in northern Guam (JRM 2016, 95 pp.). The Habitat Management Unit and the Finegayan area were both surveyed for this species. None were found in the HMU (JRM 2016, p. 5), while 29 were recorded from the area of 1,213-acre area of Finegayan described in the analysis for *Bulbophyllum guamense*, above. These areas of northern Guam contain mixed habitat types, some of which are similar to the habitat types that occur within the proposed areas to be cleared for the Cargo Drope Zone portion of this action – namely, mixed secondary limestone forest with overlap of species composition. In southern Guam, this species was commonly found as an epiphyte on Pandanus tectorius (JRM 2016, p. 9), which does occur within the proposed project footprint.

While no formal surveys have been done within the project footprint, based on the information above, and the vegetation characteristics of the action area, it is possible that a small number of *D. guamense* individuals may occur within the action area. Therefore, while the exact number of *D. guamense* that would be disturbed by this action is unknown, we do not anticipate more than 5 individuals would be impacted by this action. It is also possible that no individuals will be impacted.

Note on *Psychotria malaspinae*

While the Army requested to consult formally on *Psychotria malaspinae*, little information was available at the time to determine whether this species was likely to be present in the action area. The Service agreed to consult based on information in the Biological Assessment suggesting that this species may be present, despite no surveys of the action area (94th AAMDC 2016). However, recent information gained from discussions with local botanists, as well as reconnaissance surveys by the Service, strongly suggest that this species does not occur within the action area. *P. malaspinae* is a rare species of shrub currently known from "cockpit karst" habitats of native limestone forest (JRM 2016; pp. 6-7). In fact, only seven individuals are known from the deep karst areas, away from forest edges, on the Ritidian clifflines (E. Demeulenare, 2016, pers. comm.), in addition to two occurrences in native limestone forest elsewhere in northern Guam. This habitat type does not exist in the action area, and the small pockets of less disturbed vegetation to be impacted by this project (more detailed vegetation and habitat descriptions of the action area found in the analyses for orchids above), while they contain native tree and shrub species, do not have the topographic and ecological characteristics that typify the very small range of known habitat for this species. Therefore, we do not, at this time, analyze effects from the proposed action to *P. malaspinae*.

Figure 5. Photos of forested area proposed for clearing. *Tristiropsis obtusangula* tree in right panel.

CUMULATIVE EFFECTS

Cumulative effects include the effects of future non-Federal actions that are reasonably certain to occur within the area of action subject to consultation. Future Federal action will be subject to the consultation requirements established in section 7 of the ESA and, therefore, are not considered cumulative for the proposed action.

Although there are no proposed development projects that we are aware of, it is reasonable to assume development on Guam will continue to increase. This may increase habitat loss and degradation of suitable recovery habitat for listed species. The action area is completely within a military base, so non-Federal actions are extremely unlikely to occur within or near the action area. The staffing necessary for construction and operation of the THAAD have already caused a small increase in the number of personnel on AAFB and workers necessary for construction of the proposed portions of this actions may also contribute a small increase in population. However, a total staff of 225 mostly military personnel, with a potential 168 dependents is unlikely to result in noticeable increases in development or strains on natural resources.

CONCLUSION

In conclusion, this action is not likely to result in jeopardy to listed species analyzed above because of the amount of habitat to be cleared or disturbed constitutes a very small portion of the recovery habitat needed for recovery of these listed species. Adverse effects will be minimized by adhering to the avoidance and minimization measures detailed above. Adverse effects will also be mitigated by conservation actions detailed in the conservation measures, especially the habitat conservation and enhancement planned for 334.7 acres of potential listed species habitat on AAFB.

INCIDENTAL TAKE STATEMENT

Section 9 of the Act and Federal regulations pursuant to section 4(d) of the Act prohibit the take of endangered or threatened species, respectively, without special exemption. Take is defined as harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to engage in any such conduct. Harm is further defined by the Service to include significant habitat modification or degradation that results in death or injury to listed species by significantly impairing essential behavioural patterns, including, breeding, feeding, or sheltering. Harass is defined by the Service as intentional or negligent actions that create the likelihood of injury to listed species to such an extent as to significantly disrupt normal behaviour patterns which include, but are not limited to, breeding, feeding or sheltering.

Incidental take is defined as take that is incidental to, and not the purpose of, carrying out an otherwise lawful activity. Under the terms of section 7(b)(4) and section 7(o)(2), taking that is incidental to and not intended as part of the agency action is not considered a prohibited taking under the Act provided that such taking is in compliance with the terms and conditions of this Incidental Take Statement.

The measures described below are non-discretionary, and must be undertaken by the U.S. Army so that they become binding conditions to the applicant for the exemption in section 7(o)(2) to apply. The Army has a continuing duty to regulate the activity covered by this incidental take statement. If the Army (1) fails to assume and implement the terms and conditions or (2) fails to require contractors to adhere to the terms and conditions of the incidental take statement through enforceable terms that are added to contract documents, the protective coverage of section 7(o)(2) may lapse. In order to monitor the impact of incidental take, the Army must report the progress of the action and its impact on the species to the Service as specified in this incidental take statement [50 CFR 402.14(i)(3)].

Amount or Extent of Take Anticipated

Based on the analysis presented in this biological opinion, while adverse effects to Mariana fruit bats, Guam kingfisher, Guam rail, and Marianas crow are anticipated through loss of acres of recovery habitat, the Service does not anticipate any take in the form of mortality, harassment, or harm over the duration of the proposed action.

REINITIATION – CLOSING STATEMENT

This concludes formal consultation on this action. As required in 50 CFR §402.16, reinitiation of consultation is required where discretionary Federal agency involvement or control over the action has been retained (or is authorized by law) and if: (1) the amount or extent of incidental take is exceeded; (2) new information reveals effects of the agency action that may affect listed species or critical habitat in a manner or to an extent not considered in this opinion; (3) the agency action is subsequently modified in a manner that causes an effect to the listed species or critical habitat not considered in this opinion; or (4) a new species is listed or critical habitat designated that may be affected by the action. In instances where the amount or extent of incidental take is met, any operation causing such take must cease pending reinitiation.
If you have questions regarding this letter, please contact Jacqueline Flores, Biologist, (phone: 671-989-6744).

Sincerely,

for Mary M. Abrams, Ph.D.
Field Supervisor

Introduction

Section 7(a)(2) of the Endangered Species Act of 1973, as amended (ESA; 16 U.S.C. 1539(a)(2)) requires each Federal agency to insure that any action they authorize, fund, or carry out is not likely to jeopardize the continued existence of any endangered or threatened species or result in the destruction or adverse modification of critical habitat of such species. To "jeopardize the continued existence" means "to engage in an action that reasonably would be expected, directly or indirectly, to reduce appreciably the likelihood of both the survival and recovery of a listed species in the wild by reducing the reproduction, numbers, or distribution of that species" (50 CFR 402.02). A Federal agency is required to consult formally with the National Marine Fisheries Service (NMFS) for marine species or their designated critical habitat or with the United States Fish and Wildlife Service (USFWS) for terrestrial and freshwater species or their designated critical habitat when that agency's action "may affect" an ESA-listed species. Federal agencies are exempt from the requirement for formal consultation if they have received from NMFS or USFWS written concurrence with a determination that an action "may affect, but is not likely to adversely affect" ESA-listed species or their designated critical habitat (see ESA Section 7 Implementing Regulations; 50 CFR 402).

This document represents NMFS' biological opinion (Opinion) of the effects on marine species protected under the ESA that may result from the Guam and CNMI Military Relocation. This Opinion is based on: the review of the U.S. Navy's November 2009 Draft Environmental Impact Statement/Overseas Environmental Impact Statement - Guam and CNMI Military Relocation - Relocating Marines from Okinawa, Visiting Aircraft Carrier Berthing, and Army Air and Missile Defense Task Force (DEIS/OEIS); the U.S. Navy's March 12, 2010 Biological Assessment for Carrier Vessel Nuclear (CVN) Wharf Construction and Navy Waterfront Improvement, Apra Harbor, Guam (BA); the U.S. Navy's April 14, 2010 response to NMFS/PRD's request for additional information; recovery plans for U.S. Pacific populations of listed sea turtles; published and unpublished scientific information on the biology and ecology of threatened and endangered marine species, as well as of other species of concern in the action area; monitoring reports and research in the region; biological opinions on similar actions; and relevant scientific and gray literature (see Literature Cited).

1 Consultation History

On October 30, 2008, NMFS Pacific Islands Regional Office (PIRO) Protected Resources Division (PRD) received the Navy's October 27, 2008, request for informal consultation and concurrence with their species list, green sea turtles (*Chelonia mydas*) and hawksbill sea turtles (*Eretmochelys imbricata*), for proposed construction of berthing for nuclear-powered aircraft carriers (CVN) in Apra Harbor, Guam. On November 4, 2008, NMFS PRD conditionally concurred with the species list, based on the understanding that the proposed action area was limited to Apra Harbor, and requested additional information. Numerous interagency meetings and document reviews transpired between that date and July 29, 2009, when the Navy released the early release DEIS/OEIS for the proposed action. Among other comments, NMFS responded that we would not concur with the Navy's intended determination that the proposed action was not likely to adversely affect ESA-listed marine species, and recommended that the Navy enter into formal consultation for the proposed action for impacts on green and hawksbill sea turtles. On November 9, 2009, NMFS received the Navy's November 5, 2009 request for informal consultation. NMFS transmitted our letter of non-concurrence on December 2, 2009, stating our

rationale and again recommending the Navy request formal consultation. On March 12, 2010, the Navy hand-delivered its request for formal consultation along with its BA, both dated that same day. NMFS transmitted to the Navy our comments on the BA and a request for additional information on March 26, 2010. The requested information arrived on April 14, 2010, and a formal consultation was initiated on that date for green and hawksbill turtles. A draft Opinion was presented to the Navy on June 5, 2010. Comments on the draft Opinion were received from the Navy on July 1, 2010. The Navy's Final EIS (FEIS) for the proposed action was received on July 26, 2010. The Navy's comments and FEIS were both considered in finalizing this Opinion.

2 Description of the Proposed Action and Action Area

The proposed action is described in the Navy's March 12, 2010 BA (USN 2010a), in the April 14, 2010 additional information (USN 2010b), and in the July 2010 FEIS/OEIS (USN 2010e). In summary, the proposed action includes three primary components: 1) Relocating US Marines from Okinawa to Guam; 2) Increasing and upgrading vessel berthing and related facilities in Apra Harbor to accommodate increased visits by aircraft carriers and their accompanying ships, collectively referred to as a Carrier Strike Group (CSG), as well as supporting increased visits by Amphibious Taskforce (ATF) ships; and 3) Stationing an Army Air and Missile Defense Task Force on Guam. The proposed action includes substantial new upland construction and infrastructure improvements to support the incoming Marine and Army forces. That construction is not expected to directly affect ESA-listed species under NMFS jurisdiction. However, work done to increase and upgrade vessel berthing and related facilities in Apra Harbor is likely to directly affect ESA-listed marine species. The proposed action is expected have indirect impacts on ESA-listed marine species through increased wastewater discharge and increased commercial and recreational vessel traffic that are expected result from the proposed population increase on Guam. As such those actions are the components of the proposed action that are the subject of this consultation.

Accommodating a proposed increase in the number of military vessels visiting Apra Harbor is the prime reason for increasing and upgrading vessel berthing and related facilities in Apra Harbor. The Navy expects that visits by CSGs (typically 5-7 surface vessels and 2 submarines) would increase from the current two 7-day visits per year, to three 21-day visits per year (total of 63 days). The Navy also expects that visits by ATFs (typically 7 vessels) would increase from two 21-day visits per year, to between four and six 21-day visits per year (a maximum total of 126 days). ATFs embark numerous landing craft, which are expected to be kept at the amphibious craft laydown area at Polaris Point.

Increasing and upgrading vessel berthing and related facilities in Apra Harbor can be divided into two primary components: 1) CVN Wharf Construction and 2) Inner Harbor Waterfront Improvements. The Navy expects that work would begin in 2010. The Navy reported in their comments on the draft Opinion and their FEIS that they are deferring finalizing the decision about locating the CVN Wharf until additional marine surveys are completed. They also reported that construction of the CVN wharf would begin no earlier than FY 2013. However, they also restated that constructing the CVN Wharf at Polaris Point remains the preferred alternative. As such, construction of the CVN wharf at Polaris Point, along with its associated dredging, remains part of the proposed action, and consequently, must be analyzed in this Opinion.

The expected project-specific durations for work in Apra Harbor are given below. A great deal of overlapping work is expected, so those duration estimates are not necessarily additive in nature. No Apra Harbor-specific project completion date was given, and the DEIS/OEIS indicated that construction for the whole proposed action would be completed by 2020. Thus, although it seems likely that much of the proposed work would be done as soon as possible, some level of project-related construction may be ongoing in Apra Harbor for up to 10 years. Construction, pile driving, and dredging would be done by land-based and barge mounted heavy equipment, as appropriate, throughout the duration of the proposed project. Small support craft and divers are also expected to be used to perform construction-related tasks and repairs to equipment as needed. It is expected that pile driving and dredging, and much of the other work would be done around the clock, 7 days per week until the proposed action is completed.

2.1 CVN Wharf Construction

The primary requirements to accommodate a visiting CVN include appropriately wide channels with adequate water depth and a 1,325-foot long concrete decked wharf. To meet the required widths, the existing Navy operation channel would be widened from its current 400 feet (ft) (122 m) to 600 ft (183 m), and a 2,184-ft (666 m) diameter turning basin would be established adjacent to the proposed CVN Wharf at Polaris Point. Work to widen the channel and establish the turning basin would consist of relocating several existing channel markers, two sets of range lights, and a mooring buoy. The minimum required water depth for CVN movement is -49.5 ft (-15.1 m) mean lower low water (MLLW) plus 2 ft overdredge. The current minimum channel depth is -35 ft (-10.7 m), and the location for the proposed CVN pier is also too shallow. Consequently, the channel, turning basin, and the proposed wharf area would be mechanically dredged to -51.5 ft MLLW. The current minimum channel depth is reportedly -35 ft (-10.7 m) MLLW. However, the FEIS reports that throughout most of the project area the substrate is between 1.6 and 3.3 ft (0.5 to 1.0 m) shallower than the required -51.5 ft.

The Navy proposes to use barge-mounted equipment to dredge shallow areas within the channel, the turning basin, and at the proposed CVN wharf. The dredging footprint encompasses a total planar area of about 53 acres, including up to a maximum of 33 acres of coral reef habitat. The Navy anticipates using a several-ton steel spike chisel to fracture hard reef substrates, and a clamshell drop bucket, also several tons, to remove hard and soft substrate material. Dredging is expected to require up to 18 months of round-the-clock work to complete. Total volume of fill to be removed is about 608,000 cubic yards (yd^3) (465,000 m^3). The Navy estimates that up to 2 barge loads of dredged material would be removed per day. Dredged material would be disposed of via beneficial use options, upland dewatering and disposal, or at the US Environmental Protection Agency's (USEPA) proposed Ocean Dredged Material Disposal Site (ODMDS), which is expected to be located about 12 miles (20 km) northwest of the entrance to Apra Harbor.

The CVN wharf would be constructed at Polaris Point, at the north side of the entrance to the inner harbor. In addition to the dredging mentioned above, the shoreline along the proposed wharf alignment would be sloped to accommodate the project design. About 410 24-inch (61 cm) diameter vertical steel pipe pilings would be impact driven to about 150 ft below the mud line to support a concrete-decked wharf. Pile driving is expected to take about 2,050 hours of work to complete. Assuming 24-hour work days, it would take a minimum of about 85 days of

pile-driving. The Navy intends to underlay the length of wharf with a 3 to 1 sloped riprap structure that would extend from the shoreline under the wharf and outward to about 20 ft beyond the outermost pilings at about -50 ft. Other work would include over- and near-water work to construct the concrete decking; to install mooring structures such as bollards, cleats, and fenders; and to construct the facilities, structures, and utilities needed to support a visiting CVN.

2.2 Inner Harbor Waterfront Improvements

Proposed inner harbor waterfront improvements include: repairs and upgrades at numerous wharves; maintenance dredging; construction of an amphibious craft laydown area with ramps for launching and recovering amphibious craft and small boats; and the relocation of certain existing facilities such as the Military Working Dog Kennel and US Coast Guard facilities to make room for ATF-related facilities. Proposed improvements common to all of the wharves include: over- and near-water work to repair or replace concrete decking, ladders, and handrails; filling of voids, repair or replacement of mooring structures; the repair or replacement of wharf-side structures and utilities; and the pier-side construction of a new cargo staging area and a new equipment wash down area.

Sierra, Tango, Uniform, and Victor Wharves require significant in-water work to repair and reinforce them. All four wharves would have new sheet piling bulkheads driven-in about 10 ft seaward along the entire length of their existing bulkheads (Table 1). The new piling bulkheads would consist of 23.6-inch by 0.35-inch sheet pilings impact driven to about 66 ft below the mud line. The sheet pilings would be supported by 3-ft by 1.5-ft H-pilings that would be spaced about 10 ft apart and driven to 75 ft below the mud line. The new bulkheads would be tied-back to the existing wharf bulkheads and additional H-pilings driven between the existing and new bulkheads. Pile driving is expected to take about 18 months of 24-hour work days to complete. The voids between the new and old bulkheads would be filled, and new concrete decking would be constructed out to the new bulkheads.

Table 1. Details for work at S, T, U, & V Wharves, including the number of pilings and expected duration of work.

Wharf	Length	Sheet Piles	Support H Piles	Tie-back H Piles	Pile Drive Duration	Total Project Duration
Sierra	660 yards	360	170	390	3 to 6 months	9 months
Tango	520 yards	370	180	400	3 to 6 months	9 months
Uniform	220 yards	185	80	190	3 months	6 months
Victor	220 yards	200	98	186	3 months	6 months

In order to accommodate the operational requirements of the ATF vessels that would berth in the inner harbor, the harbor floor in front of S and T wharves must be dredged from the current depth of -35 ft (-10.7 m), down to -40 ft (-12.2 m) MLLW. The Navy proposes to use barge-mounted equipment with a clamshell bucket to mechanically remove about 327,000 yd^3 (250,000 m^3) of accumulated fine sediments. The dredging footprint encompasses about 114 acres. The Navy estimates that up to 12 months of dredging would be required, and that up to 2 barge loads of dredged material would be removed per day. As with the CVN-related dredging, material dredged from the inner harbor would be disposed of via beneficial use, upland disposal, or at the ODMDS.

2.3 ODMDS Disposal Option

About 935,000 yd^3 of dredged material is expected to be produced over about 21 months for inner and outer harbor dredging projects combined. Assuming that the USEPA designates its proposed Guam ODMDS in 2010, as planned, it is likely that a significant volume of that dredged material would be disposed of at the ODMDS, requiring up to 234 round trips by tugs and scows to deliver the dredged material to the ODMDS.

2.4 Best Management Practices (BMPs)

The BMPs enumerated in Navy's Biological Assessment are intended to ensure that constant vigilance shall be kept for the presence of ESA-listed sea turtles during all aspects of the proposed construction action, particularly during in-water activities such as pile driving, dredging, boat operations, or diving. They are also intended to minimize contamination of the marine environment from project-related activities. Such measures include, but are not limited to, protected species safety zones, ramp up protocols, vessel speed limits, construction debris control, and the use of turbidity and siltation minimization devices. In their April 14, 2010 response to NMFS/PRD's request for additional information, the Navy committed to incorporate a list of BMPs intended to further reduce or eliminate project-related impacts on ESA-listed marine species.

2.5 Interrelated/Interdependent Actions

For the purposes of this consultation, interrelated and interdependent actions due to the overall proposed action are actions related to supplying the construction and supporting the increased population that may be expected to impact the marine environment. As such interrelated and interdependent actions are expected to include: 1) increased commercial shipping traffic; and 2) increased discharge of wastewater effluent.

The other major components of the proposed action, relocating US Marines to Guam and stationing a US Army Air and Missile Defense Task Force on Guam would increase the human population on Guam, which is currently about 180,000 people (CIA 2010). Personnel would be permanently relocated to Guam, and temporary construction works would move to the island to support the related construction, but are expected to leave when work is no longer available. As described in the DEIS, the maximum additional population is expected to peak at about 79,000 people in 2014 during the height of construction (a 43.9 % increase over the current population). Following the peak, the additional population is expected to decline and level off at about 33,600 additional people by 2019 (an 18.7 % increase over the current population). Additionally, CSG and ATF visits are expected to periodically bring about 7,200 and 6,200 more personnel to Guam, respectively (USN 2010e).

In their comments on the Draft Opinion, and in the FEIS, the Navy described the potential implementation of Force Flow Reduction (FFR) and an Adaptive Program Management (APM) approach that could be used in conjunction with each other to avoid the growing population's exceedance of infrastructure capability. The Navy could adjust the arrival of the majority of the relocated military personnel (FFR) until much of the construction was completed and the number of on-island temporary construction workers was in decline. The APM, through its advisory body the Civil-Military Coordination Council, would be used monitor environmental impacts and infrastructure capacities so that construction tempo and sequencing could be adjusted to

minimize environmental impacts. The Navy suggests that the combination of FFR and APM could reduce the peak population increase from 79,000 in 2014, to something close to 41,000 across the 2014 to 2018 time frame, but they are clear that the numbers given are only notional, and they make no commitments to any specific levels or dates. The post-construction population increase would remain as described in the FEIS, but the additional population may not drop to that level until 2020. Implementation of FFR and APM could reduce environmental impacts as compared to those expected to result from the proposed action, as described in the DEIS. However, without a commitment from the Navy to achieve/maintain particular population levels, or to complete specific infrastructure upgrades, NMFS must assume that potential impacts due to the expected population increase would occur based on a population growth curve that is somewhere between that described in the FEIS (79,000 peak) and the one described in their FFR/APM plan (41,000 peak). As such, NMFS assessed potential impacts based on the 79,000 population peak described in the DEIS, under the assumption that that level would be a worst case scenario, and that this approach would allow an appropriately conservative analysis.

1. The FEIS reports that total annual commercial shipping (containerships and breakbulk/Roll-On-Roll-Off (RORO) ships, and barges) has steadily declined from a high of 763 vessels in 1995 to a low of 436 vessels in 2008. Although breakbulk/RORO and barge arrivals declined during that period, containership arrivals increased, particularly during 2007 and 2008. Barge traffic has fallen off dramatically, to about 20 trips annually since 2006, and the FEIS did not predict any increase in that traffic. However, the FEIS predicts that breakbulk/RORO and containership arrivals would increase at the onset of construction. It is likely that the increase has already begun, but this consultation can only address components of the action that are yet to occur. The 14-year averages (1995-2008) for breakbulk/RORO ships and containership arrivals are 290 and 124, respectively. The combined average is 414 annual trips. The FEIS reports that, due to construction, annual commercial traffic is expected to rise to 58 additional arrivals in 2010, peak at 362 additional arrivals in 2015, and then taper-off, back down to the 14-year average toward the completion of construction in 2018. Although recent shipping trends seem to be downward and the FEIS suggests that commercial shipping would fall back down to pre-action levels, NMFS expects post-construction commercial shipping to level-off at a rate commensurate with the expected permanent population increase (19%). Thus, about 79 additional commercial ships (breakbulk/RORO ships and containerships combined) are expected to arrive annually following the end of construction.

2. Wastewater effluent discharged into the waters of Guam is expected to increase proportionally to the population increase. Based on expected population changes, as described in the FEIS, the population could increase by about 45% above 2010 levels in 2014, during the construction peak, then taper off to about 19% above 2010 levels in 2019 and beyond (factoring in increases due to CSG and ATF visits). Wastewater effluent discharged by the Northern District Wastewater Treatment Plant (NDWTP) is expected to increase by 5.6 million gallons per day (MGD); a 46.7% increase (USN 2010e). Effluent discharged by the Hagatna WTP is also expected to increase due to the proposed action but not as much as the NDWTP.

2.6 Action Area

With regard to ESA-listed marine species under NMFS jurisdiction, the action area for the Guam and CNMI Military Relocation is defined as the marine waters around the Island of Guam out to about 5 nautical miles (nm) where the direct and indirect impacts from harbor construction, increased shipping, effluent outflow, and recreational use of marine waters are expected to be contained (Figure 1).

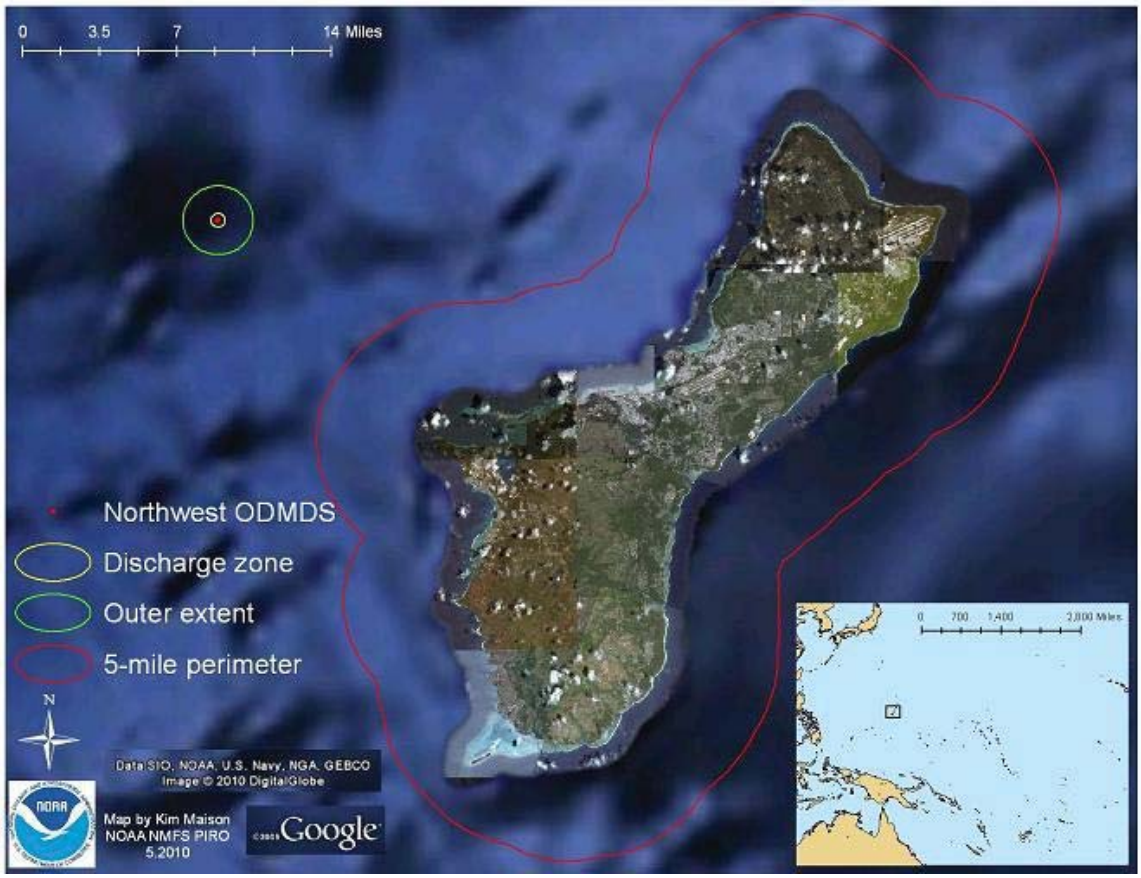

Figure 1. Action Area - Guam with the 5-mile nearshore area outlined in red, and the proposed USEPA Ocean Dredge Material Disposal Site (ODMDS) outlined in green.

Should the Guam ODMDS option be exercised for the disposal of dredged material during the proposed action, the action area is further extended to include the in-water area approximately 110 yards around the tugs and scows as they transit to and from the ODMDS, as well as the area around and under the tug and scow when disposal takes place. Also, due to the increased commercial shipping and military vessel traffic that would not approach Guam if it were not for the proposed action, the action area must also include the in-water area around those additional vessels. For the additional commercial vessels, the action area includes the in-water area approximately 110 yards around those ships as they transit to and from Apra Harbor once inside the 200 nm boundary of the Guam Exclusive Economic Zone (EEZ) (NMFS 2010b).

The movement of additional military vessels in and out of Apra Harbor is more complicated. Military vessels typically conduct training while enroute. With the exception of some land based small arms fire and other strictly land based training, military training in the Marianas is intentionally excluded from the proposed action. All other significant military training in the Marianas, such as naval exercises and amphibious landings is covered under the EIS/OEIS for the Mariana Islands Range Complex (MIRC) and the potential impacts of that training are considered in a separate ESA consultation. Thus, the action area around additional military vessels includes the in-water area approximately 110 yards around those ships, but begins only when training covered under the MIRC is complete and those vessels are headed for port in Apra Harbor. Similarly, the action area around outbound military vessels is considered terminated upon the initiation of training that is covered under the MIRC.

3 Status of the Species

The US Navy determined that the proposed action is likely to adversely affect green and hawksbill turtles, but that the action would have no effect on blue, fin, humpback, sei, and sperm whales, as well as leatherback, loggerhead and olive ridley sea turtles (USN 2010c). However, due to expected actions that are interrelated and interdependent to the proposed action, particularly the expected increased vessel traffic to and from the Marianas, NMFS has determined that the proposed action may affect, but is not likely to adversely affect blue, fin, humpback, sei, and sperm whales, as well as leatherback, loggerhead and olive ridley sea turtles (Table 2). Green and hawksbill turtles are the subject of this Opinion.

Table 2. ESA-listed marine species that may be affected by proposed action.

Species	Scientific Name	ESA Status	Listed	Federal Register
Species not likely to be adversely affected by the proposed action.				
Blue Whale	*Balaenoptera musculus*	Endangered	12/02/1970	35 FR 18319
Fin Whale	*Balaenoptera physalus*	Endangered	12/02/1970	35 FR 18319
Humpback Whale	*Megaptera novaeangliae*	Endangered	12/02/1970	35 FR 18319
Sei Whale	*Balaenoptera borealis*	Endangered	12/02/1970	35 FR 18319
Sperm Whale	*Physeter macrocephalus*	Endangered	12/02/1970	35 FR 18319
Leatherback Sea Turtle	*Dermochelys coriacea*	Endangered	06/02/1970	35 FR 8491
Loggerhead Sea Turtle	*Caretta caretta*	Threatened	07/28/1978	43 FR 32800
Olive Ridley Sea Turtle	*Lepidochelys olivacea*			
Nesting aggregations on west coast of Mexico		Endangered	07/28/1978	43 FR 32800
All other Olive Ridley Sea Turtles		Threatened	07/28/1978	43 FR 32800
Species likely to be adversely affected by the proposed action.				
Green Sea Turtle	*Chelonia mydas*			
Nesting aggregations in Florida and Mexico		Endangered	07/28/1978	43 FR 32800
All other Green Sea Turtles		Threatened	07/28/1978	43 FR 32800
Hawksbill Sea Turtle	*Eretmochelys imbricata*	Endangered	07/28/1978	43 FR 32800

This section presents biological or ecological information for green and hawksbill sea turtles affected by the proposed action relevant to formulating the Opinion. Subsections 3.1 and 3.2 provide species-specific descriptions of distribution and abundance, life history characteristics (especially those affecting vulnerability to the proposed action), threats to the species, major conservation efforts, and other relevant information. Factors affecting those species within the action area are described in more detail in the Environmental Baseline (Section 4). No critical habitat has been designated for either of these species in the Pacific Ocean. Therefore, this project would have no effect on designated critical habitat under NMFS jurisdiction.

3.1 Green Sea Turtles

Green turtles are distributed circum-globally, and can be found in the Pacific, Indian, and Atlantic Oceans as well as the Mediterranean Sea, as described in the most recent green turtle 5-year status review (NMFS & USFWS 2007a). As shown above in Table 2, in 1978, all green turtles were listed as threatened under the ESA, except for the breeding populations in Florida and on the Pacific coast of Mexico, which were listed as endangered. Following are descriptions of the distribution and abundance, life history characteristics (especially those affecting vulnerability to the proposed action), threats to the species, and major conservation efforts for green sea turtles.

3.1.1 Distribution and Abundance

Globally, most green sea turtle nesting populations declined substantially during the 20th century. Conservation efforts over the past 25 years or more appear to have had some positive results, as indicated below. However, threats and impacts persist for many green sea turtle populations (NMFS & USFWS 2007a). Following are brief descriptions of distribution and abundance of green turtles in the three major ocean basins, with more detail provided for Oceania in the Pacific Basin where the action area is located. These descriptions are based on the numbers of nesting females, or their nests, because those are the best available methods for confirming sea turtle distribution or for estimating density and population trends.

Indian Ocean

There are numerous nesting sites for green sea turtles in the Indian Ocean. One of the largest nesting sites for green sea turtles worldwide occurs on the beaches of Oman where an estimated 20,000 green sea turtles nest annually. Based on a review of 32 index sites, declines in green turtle nesting were evident for many of the Indian Ocean index sites (Seminoff 2004). While several of these had not demonstrated further declines in the more recent past, Comoros Island and the Seychelles are the only index sites in the western Indian Ocean that showed evidence of increased nesting (NMFS & USFWS 2007a).

Atlantic Ocean / Mediterranean Sea

The 5-year status review for the species identified nine geographic areas considered to be primary sites for green sea turtle nesting in the Atlantic/Caribbean, and four in the Mediterranean and reviewed the trend in nest count data for each (NMFS and USFWS 2007a). Atlantic areas include: (1) Florida, USA; (2) Yucatán Peninsula, Mexico; (3) Tortuguero, Costa Rica; (4) Aves Island, Venezuela; (5) Galibi Reserve, Suriname; (6) Isla Trindade, Brazil; (7) Ascension Island, United Kingdom; (8) Bioko Island, Equatorial Guinea; and (9) Bijagos Archipelago (Guinea-Bissau). Mediterranean sites include: (1) Turkey; (2) Cyprus; (3) Israel/Palestine; and (4) Syria. Nesting at all of the Atlantic sites was considered to be stable or increasing with the exception of Bioko Island and the Bijagos Archipelago where the lack of sufficient data precluded a meaningful trend assessment for either site. Lack of sufficient data also precluded meaningful trend assessments for the Mediterranean sites. The most important nesting concentration for green turtles in the Atlantic is at Tortuguero, Costa Rica, where nesting has increased since the 1970s. Nest count data from 1999-2003 suggest nesting by 17,402- 37,290 females per year. These sites are not inclusive of all green sea turtle nesting in the Atlantic or Mediterranean. However, other sites support lower levels of nesting and contribute a much smaller proportion to the total number of green turtles in these areas (NMFS and USFWS 2007a).

Pacific Ocean

Green turtles occur in the eastern, central, and western Pacific. Foraging areas are found throughout the Pacific, including along the southwestern U.S. coast (NMFS and USFWS 1998a). Nesting is known to occur at hundreds of sites throughout the Pacific, with major nesting occurring in Indonesia, Malaysia, the Philippines, Australia, Micronesia, Hawaii, New Caledonia, Mexico, the Galapagos Islands, and other sites (NMFS & USFWS 2007a). Oceania is a subset of the Pacific, and includes Micronesia (where the action area is located), Melanesia, and Polynesia. In this opinion, Oceania is defined as also including Australia's Great Barrier Reef (GBR), because a high proportion of green turtles occurring in Oceania nest on the GBR. Based on the best information currently available, about 18,000 to 38,000 green turtles nest annually in Oceania (Figure 2) (NMFS 2010a).

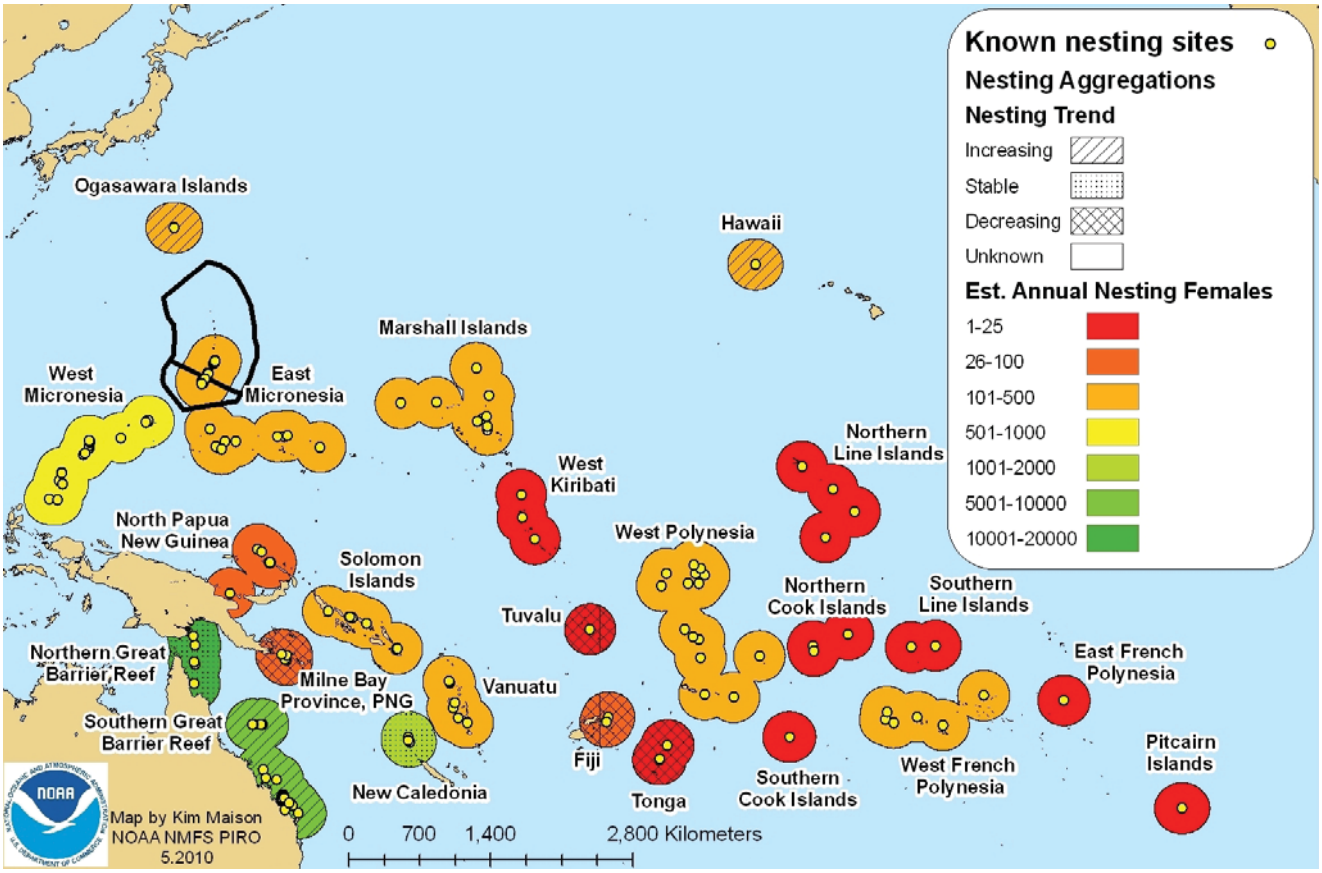

Figure 2. Green turtle nesting aggregations in Oceania. Mariana EEZs are outlined in black.

However, about 90% of nesting takes place among two Australian nesting aggregations (NAs) (Northern GBR and Southern GBR which includes the Coral Sea Platform), with over half of all the nesting occurring on a single island; Raine Island in the Northern GBR (Chaloupka *et al*. 2008a, Limpus 2009). Nesting trends appear stable at Raine Island, and are increasing at Heron Island in the Southern GBR, as well as at Chichi-jima in the Ogasawara Islands (Chaloupka *et al*. 2008a). However, these trends do not necessarily correlate with a stable or increasing total number of turtles because of low nesting success and hatchling production at Raine Island, where the majority of nesting for Oceania occurs (Limpus *et al*. 2003; Limpus 2009). Also, NAs with small numbers of nesting females, like those throughout the islands and atolls of central and

south Pacific, may be of greater importance than their proportional numbers indicate. Many of these NAs are geographically isolated, and likely harbor unique genetic diversity, which may be lost if these small NAs or their components become extirpated (Avise & Bowen 1994).

Mariana Archipelago

Sub-adult and adult green turtles occur in low abundance in nearshore waters around the Mariana Islands. Although it is likely that they occur around all of the Mariana Islands, nesting is thought to occur only in the southern islands of the CNMI and on Guam. There are no reports of turtles nesting at northern island locations. Genetic samples from nesting rookeries in the western Pacific Islands suggest that nesting greens in Guam and the CNMI are indistinguishable from each other, but distinct from those in Palau, Yap and the Marshall Islands (Dutton 2009).

Kolinski *et al*. (2004) estimated 1,000 to 2,000 turtles inhabit reef areas in the southern CNMI (Rota, Tinian, Aguiguan, Saipan, and Farallon de Mendillia). Information on nesting trend is currently insufficient for the CNMI. However, anecdotal information from residents suggests that nesting activity has decreased over time, likely as a direct result of illegal harvest (NMFS and USFWS 2007a). Since 1999, the CNMI Division of Fish and Wildlife (DFW) has monitored nesting at a minimum of five beaches on Saipan (CNMI DFW 2009), where between 4 and 18 nests are laid annually (CNMI DFW unpublished annual reports). Monitoring on Saipan, between March 4 and August 31, 2009, confirmed 16 green turtle nests, but also confirmed that three nesting turtles and three nests were poached during the same time (CNMI DFW 2009). On Tinian, nesting likely occurs on all or most of the accessible beaches (Pultz *et al*. 1999), and a July 22-31, 2009 rapid assessment yielded 35 nests at 5 beaches (CNMI DFW 2009). Eleven beaches on Rota are known to support nesting (Ilo *et al*. 2005), and a rapid assessment on July 12, 2009 yielded 13 nests (CNMI DFW 2009).

On Guam, the 5-year status review for green sea turtles reports that nesting was stable between 1990 and 2001 with the number of annual nesters fluctuating between 2 and 60 females, with nearly constant near shore abundance 150 to 250 turtles (NMFS and USFWS 2007a). Foraging and resting green turtles are often seen in close proximity to seagrass beds and reef flats, including Cocos Lagoon, Apra Harbor, Tarague Beach and several other locations around the island (Wiles *et al.* 1995). Guam's Division of Aquatic Wildlife Resources (DAWR) has maintained a bimonthly aerial survey program to monitor near shore fisheries and record opportunistic animal sightings, including marine turtles. These surveys confirm the year-round presence of a resident population of green sea turtles in Guam's nearshore waters. A total of 351 sea turtles were observed during aerial surveys between 1998 and 2008, with an annual mean of 32 turtles. Sightings include low numbers of turtles observed in the area of the proposed CVN turning basin and in inner Apra Harbor (DAWR unpublished data).

Information is currently inadequate to identify or define in any comprehensive manner green turtle in-water habitat resources around Guam, or to describe its utilization in more than general terms. However, for the purposes of this consultation, NMFS has defined potential green turtle habitat as the in-water marine areas around Guam from the shoreline to a depth of 100 feet (30.5 m), including Apra Harbor and Cocos Island lagoon. This was done with the intention of including habitat areas most likely to possess features beneficial to green turtles for foraging and refugia, such as: hard reef areas that support algal growth; shallow sandy areas that support

seagrass growth; vertical structures with fissures, caves, and over-hangs that would provide shelter; and the overlying waters necessary for turtles to transit between their various habitats. Although green turtles are rarely seen inside the shore break around Guam, this does not exclude that area as potential turtle habitat that may be utilized as the population recovers into the future. For example, high numbers of the recovering green turtle population in Hawaii are regularly observed in nearshore reef habitats inside of the shore break, including basking on the beach. Based on bathymetric information, the area around Guam between the shoreline and the 100-ft depth curve encompasses about 36 square miles (23,000 acres, 93 km2).

Opportunistic nesting surveys counted 55 green turtle nests at various beaches around Guam between October 1, 2006 and July 31, 2008 (GDAWR 2009). Known nesting beaches on Guam include: Ritidian National Wildlife Refuge, Haputo, Urunao, Tumon Bay, Cabras Island, Spanish Steps (Dangkolo and Dikiki), Cocos Island, Acho Bay, Nomña Bay, Jinapsan, and Tarague Beach (GDAWR 2004; Grimm and Farley 2008). Of these beaches, two locations are on Navy lands: Haputo, and Spanish Steps, with an additional 6 to 8 unmonitored beaches occurring on Navy lands (Grimm and Farley 2008). Nesting activity peaks from April to July on Guam but often appears to continue throughout the entire year (Grimm and Farley 2008).

Little data exists regarding the number of green turtles that nest on the beaches at Spanish Steps (Dikiki and Dangkolo), although it is considered one of the primary nesting locations in Guam. During 2007 and 2008, Naval Facilities Engineering Command Marianas (NAVFACMAR) monitored nesting sites 3 times per week between May and July. In 2007, 5 green turtle nests were identified at Dangkolo, and in 2008, 18 green turtle nests or nest attempts were identified at the same site (Grimm and Farley 2008). Based on this limited information and assuming that a female may lay 5 to 6 clutches per season (Grimm and Farley 2008), about 1 to 4 green turtles may nest per season at Spanish Steps. Emergence success data from Raine Island, Australia and French Frigate Shoals, Hawaii suggest the mean number of eggs per clutch is 104 eggs. Emergence success rates ranged from 74-83% in Australia (Limpus *et al*. 2003) and 70% in Hawaii (Balazs 1980). Based on this information, the number of green turtle hatchlings that hatched from 18 nests at Dangkolo in 2008 may have ranged between 1,310 and 1,557 (18 nests x 104 eggs = 1872 eggs/nest x 0.70 emergence success = 1,310 hatchlings; or 1872 eggs/nest x 0.83 emergence success = 1,557 hatchlings). Using similar population parameters, the 5 green turtle nests in 2007 may have produced between 364 and 432 hatchlings.

3.1.2 Life History Characteristics Affecting Vulnerability to Proposed Action

Following hatching at their natal beaches, green turtle hatchlings spend several years of early development in the oceanic (pelagic) zone followed by recruitment to coastal areas where post-recruitment juveniles and adults forage and mature in shallow coastal areas, feeding primarily on algae and seagrass. When on their foraging grounds, post-recruitment green turtles are often referred to as “residents”. The majority of sea turtles in coastal areas spend their time at depths <5 m below the surface (Schofield *et al.* 2010, Hazel *et al.* 2009), and most resident green turtles show strong long-term site fidelity (over years) to preferred nearshore foraging and sheltering habitats, often until the habitat can no longer support their increasing size (Balazs and Chaloupka, 2004; Balazs *et al*. 1987 and 1998; Chaloupka and Limpus 2001; Godley *et al*. 2003; Grant *et al*. 1997; Seminoff *et al*. 2003). Upon reaching sexual maturity, adult greens typically undertake long migrations between their resident foraging grounds and their natal nesting areas,

where they mate and females nest. Nesting females are referred to as “nesters”, which distinguishes them from “resident” turtles that regularly forage in that area. Although males also make mating migrations, because they do not crawl out on the beach as the females do, those males are nearly impossible to distinguish from the resident males.

Green turtle forage grounds and natal nesting areas are frequently located in different island groups, and residents at a given island group may originate from multiple natal nesting areas. Between 1971 and 1996, 46 adult female greens were flipper tagged after they nested at Rose Atoll, American Samoa. Three were recaptured, two in Fiji, and one in Vanuatu (Balazs *et al*. 1994). Between 1993 and 1995 seven post-nesting green turtles were satellite tagged at Rose Atoll. Most migrated 1,600 km to foraging areas in Fiji, and one migrated to French Polynesia (Craig *et al*. 2004). Of 513 greens tagged in French Polynesia between 1972 and 1991, six were recovered in Fiji, three in Vanuatu, two in New Caledonia, and one each were recovered in Tonga, and in the Cook Islands. Five post-nesting green turtles were satellite tracked in the Republic of the Marshall Islands (RMI) in 2007-2008, one turtle migrated to Bikini Atoll, RMI, another to Tarawa Atoll in Kiribati, one traveled to the Philippines passing through the CNMI, while two turtles circled for long periods of time in the open ocean with one having a final transmitted location in the FSM EEZ and the other in RMI (PIRO and PIFSC unpublished data). The last two turtles may have been exhibiting oceanic foraging strategies (Kabua *et al.* 2009). Seven post-nesting green turtles were satellite tracked from Yap, Federated States of Micronesia (FSM) during 2005-2006. Five migrated to the Philippines, one to Malaysia, and one turtle’s transmitter ceased sending signals while still in the FSM (Kolinski *et al.* Draft manuscript 2007). An additional seven post-nesting greens were tracked from Yap in 2007: four migrated to the Ryukyu Islands of Japan and three went to the Philippines (PIRO and PIFSC unpublished data).

While information for the Marianas is limited, there is every reason to believe that turtles in the Marianas display similar life history characteristics as other green turtle populations; migrating great distances between resident forage habitats and their natal beaches were they mate and nest. Three post-nesting green turtles have been satellite tracked from Guam. One was tagged at Pati Point in 2000, and tracked to the Philippines. Two others were tracked from Cocos Island in 2007; one migrated to Japan and the other to the Philippines (S. Wusstig, pers. comm.). Because green turtles found around Guam likely migrate widely between their preferred forage and nesting areas, the proposed action may affect green turtles from multiple NAs across a broad area of the south and western Pacific (Figure 2).

Turtle hearing research is limited, but available information suggests that they are low frequency specialists, with greens thought to be most acoustically sensitive between 200 and 700 hertz (Hz) (Ridgway *et al.* 1969). Because the hearing range of green turtles overlaps with the expected frequency range of the pile driving signals, NMFS considers it likely that greens can hear and respond to pile driving noise. Existing information about sea turtle sensory biology also suggests that sea turtles rely more heavily on visual cues, rather than auditory, to initiate threat avoidance, and that they can not be expected to consistently notice and avoid vessels that are traveling faster than 2 knots (kts) (Hazel *et al*. 2007). Consequently, it is likely that green turtles would be at increased risk of vessel collision due to the expected increased vessel activity.

As described above, post-recruitment juvenile and adult green turtles forage primarily on macroalgae and seagrasses. Carrion-Cortez *et al.* (2010) found that green sea turtles in the Galapagos Islands fed mainly on algae, but also on mangrove, and possibly animal matter. Lopez-Mendilaharsu *et al.* (2005) examined green sea turtle stomach contents from turtles collected in Bahia Magdalena, Mexico and found primarily algae and sea grass species, but also invertebrate and mangrove species. Seminoff *et al.* (2006) studied green sea turtle foraging and resting behavior in the Gulf of California and found that forage species included marine algae, tube worms, and black coral polyps. The study also found that green sea turtles rested within patches of black coral, marine algae pastures, and insular boulder habitats. This suggests that reef features can be an important component of sea turtle resting microsites. Seminoff *et al.* (2002) report that green sea turtles consumed diverse marine algae, but augmented their diet with food items such as sponges. Balazs *et al.* (1987) sampled stomach contents of green sea turtles in the main Hawaiian Islands and found algae was a primary component of this species diet.

The FEIS reports that several algal species found within the proposed dredging area are known forage for green turtles, and that green turtles have been observed on the reefs adjacent to the proposed dredging area, in Sasa Bay, and in the inner harbor. The FEIS also provides survey photographs of areas in the proposed dredging area that have reef structures that may serve as turtle sheltering habitat, such as undercuts and overhanging structures. Aerial survey data from Guam DAWR reports the presence of green turtles on the surface in the proposed dredging area (DAWR unpublished). Thus, green turtles have been seen underwater and on the surface in areas adjacent to the proposed outer harbor dredging area as well as on the surface in that dredging area. Also, potential sheltering habitat and known forage resources occur in the proposed outer harbor dredging area. Based on this, NMFS considers it likely that, at a minimum, greens utilize the area as a transit corridor, and that they may yet utilize the area to some degree for sheltering and forage resources found there.

Studies show that sea turtles are adapted for bright light vision and they can see ultraviolet (UV) wavelengths (Fritsches and Warrant 2006). Although sea turtle and human vision overlaps in the visible light spectrum, violet and near-UV light sources appear brighter to turtles than to humans (Witherington & Martin 1996). Consequently, sea turtles are most attracted to shorter wavelength lights such as UV, violet, blue, and green, and less attracted to longer wavelength lights, such as yellow, amber, and red (Witherington & Martin 1996). However, it is important to add that intensity is also important; the higher the intensity, the more attractive the light. So, even longer wavelengths can be attractive when at high intensity. Sea turtle hatchlings possess an inborn tendency to move in the direction of the brightest light. Under natural conditions, starlight and moonlight brightens the sky and ocean, drawing the newly emerged hatchlings toward the sea. However, if artificial light sources are present, hatchlings often crawl toward those lights and are led away from the ocean (Witherington and Martin 1996). Artificial light on the beach may also discourage adult females from nesting (Mortimer 1983).

Based on the description of the proposed action and on green turtle life history characteristics, post-recruitment juvenile and adult green turtles sheltering and foraging in Apra Harbor are the life stages most likely to be affected by the expected high intensity noise (pile driving) and loss of forage and sheltering habitat (dredging). Post-recruitment juveniles and adults in the nearshore waters in Apra Harbor and are the life stages most likely to be affected by the increased boating

activity around Guam. Because the green turtles found around Guam are likely to migrate widely between their preferred forage and nesting areas, the proposed action may affect greens from multiple NAs across a broad area of the south and western Pacific (Figure 2).

3.1.3 Threat to the Species

Global threats to green turtles are described in the 5-year review (NMFS & USFWS 2007a). The major threats to the species are alteration of nesting and foraging habitat, fishing bycatch, and direct harvest, which are briefly described below. Climate change also appears to be a growing threat to this species, and is also mentioned below.

Destruction and alteration of green turtle nesting and foraging habitats is occurring throughout the species' global range, especially through coastal development, beach armoring, beachfront lighting, vehicular/ pedestrian traffic, invasive species, and pollution from discharges and runoff. Under natural conditions, beaches can move landward or seaward with fluctuations in sea level. However, extensive shoreline hardening (e.g., seawalls) inhibits this natural process. Beach armoring is typically done to protect the coastal development from erosion during storms, but armoring blocks turtle nesting and often leads to beach loss. Coastal development also increases artificial lighting, which may disorient emerging hatchlings, causing them to crawl inland towards the lights instead of seaward. Coastal development also improves beach access for humans, resulting in more vehicular and foot traffic on beaches, causing compaction of nests and thereby reducing emergence success. Adult green turtles are opportunistic feeders, but are considered primarily herbivores that forage on seagrass and algae in shallow nearshore areas and coral reefs. Contamination from effluent discharges and runoff has degraded these habitats, and invasive species may reduce native algae species preferred by green turtles or could exacerbate susceptibility to, or development of disease (NMFS & USFWS 2007a; Guimaraes dos Santos 2010).

Green turtles are susceptible to fisheries bycatch, particularly in nearshore artisanal fisheries. These fisheries use a vast diversity of gears, including long-lining, drift gillnets, set-nets, pound-nets, trawls, and others. Despite operating in the areas with the greatest density of adult green turtles, artisanal fisheries are typically the least regulated of all fisheries (NMFS & USFWS 2007a). Industrial fisheries such as the Hawaii-based deep-set and American Samoa longline fisheries also interact with green turtles, especially juveniles. Harvest of green turtles for their meat, shells, and eggs has been a major factor in the past declines of green turtles. Although reduced from previous levels, legal and illegal harvest of adults and eggs continues in most of the NAs described above, and remains a major factor in some parts of the species' range, including in the Marianas.

Although green turtles are probably already being affected by impacts associated with anthropogenic climate change in several ways (described in more detail in the Environmental Baseline section below), no significant climate change-related impacts to green turtle populations have been observed to date. However, over the long-term, climate change-related impacts will likely influence biological trajectories in the future on a century scale (Paremsan and Yohe 2003). For example, increasing temperatures at nesting beaches may impact sex ratios of hatchlings (many rookeries already exhibit strong female bias [Binckley *et al*. 1998; Chan and Liew 1995; Godfrey *et al*. 1996; Godfrey *et al*. 1999; Godley *et al*. 2001; Kaska *et al*. 2006;

Marcovaldi *et al*. 1997; Oz *et al*. 2004]) and/or increase embryonic mortality (Matsuzawa *et al*. 2002). Increased nest mortality has also been linked to erosion due to increased typhoon frequency (VanHoutan and Bass 2007) and intensity; predicted consequences of climate change (Webster *et al*. 2005). Seagrasses are a major food source for green turtles worldwide. Seagrass habitats may suffer from decreased productivity and/or increased stress due to sea level rise and salinity and temperature changes (Short and Neckles 1999; Duarte 2002). Climate change induced shifts in ocean productivity linked to temperature changes (Harwood 2001; Edwards & Richardson 2004; Hays *et al*. 2005) may affect foraging strategies and therefore reproductive capacity for green turtles (Solow *et al*. 2002) similar to what has been observed during El Nino events in the western Pacific (Limpus and Nicholls 1994; Chaloupka 2001). While there is some available data on past trends, this data is limited, and current scientific methods are not able to reliably predict the future magnitude of climate change and associated impacts or the adaptive capacity of this species. Due to a lack of scientific data, the specific effects climate change will have on this species in the future are not predictable or quantifiable to any degree that would allow for more detailed analysis in this consultation (Hawkes *et al*. 2009). Because of this uncertainty, climate change-related impacts are not considered significant within the context of the temporal scale of this action, as discussed further in the Environmental Baseline and Cumulative Effects sections below.

3.1.4 Conservation of the Species

Green turtles nesting in the US have benefited from both State and Federal laws passed in the early 1970s banning the harvest of turtles and their eggs. Protection and management activities since 1974 throughout the Hawaiian Archipelago and habitat protection at the French Frigate Shoals nesting area since the 1950's have resulted in increased population trends of both nesting and foraging turtles (Balazs and Chaloupka 2004). Elsewhere, the protection of nesting beaches against large-scale egg harvest appears to have reversed some downward nesting trends. Using long-term data sets, encouraging trends in green turtle nester or nest abundance over the past 25 years has become apparent in at least six locations including Hawaii, Australia, Japan, Costa Rica and Florida (Chaloupka *et al*. 2008a).

Efforts to reduce fisheries bycatch, such as the improvements made in the Hawaii-based longline fishery since the 1990s, has reduced green turtle interactions (NMFS & USFWS 2007a). Internationally, the conservation and recovery of green turtles is facilitated by a number of regulatory mechanisms at international, regional, national and local levels, such as the FAO Technical Consultation on Sea Turtle-Fishery Interactions, the Inter-American Convention for the Protection and Conservation of Sea Turtles, the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), and others. As a result of these designations and agreements, many of the intentional impacts on sea turtles have been reduced: harvest of eggs and adults have been slowed at several nesting areas through nesting beach conservation efforts and an increasing number of community-based initiatives are in place to slow the take of turtles in foraging areas (Gilman *et al*. 2007; NMFS & USFWS 2007a).

3.2 Hawksbill Sea Turtles

Hawksbill turtles are distributed circumglobally, and can be found in the Pacific, Indian, and Atlantic Oceans, but not in the Mediterranean Sea, as described in the most recent hawksbill turtle 5-year status review (NMFS & USFWS 2007b). As shown above in Table 2, in 1978, all

hawksbill turtles are listed as endangered under the ESA. Hawksbills are the most tropical sea turtle species, ranging from approximately 30° N latitude to 30° S latitude. They are closely associated with coral reefs and other hard-bottom habitats, but are also found in other habitats including inlets, bays, and coastal lagoons. There are only five remaining nesting aggregations with more than 1,000 females nesting annually. These nesting aggregations are in the Seychelles, Mexico, Indonesia, and two in Australia (NMFS and USFWS 2007b). The global population has declined by more than 80 percent over the last three generations. Hawksbills face many of the same threats affecting green sea turtles. In addition, there continues to be a commercial market for hawksbill shell products, despite protections afforded to the species under U.S. law and international conventions (NMFS and USFWS 2007b). Following are descriptions of the distribution and abundance, life history characteristics (especially those affecting vulnerability to the proposed action), threats to the species, major conservation efforts for the hawksbill sea turtle.

3.2.1 Distribution and Abundance

Globally, most of the important hawksbill sea turtle nesting populations declined substantially during the 20th century. Following are brief descriptions of distribution and abundance of hawksbill turtles in the three major ocean basins, with more detail provided for Oceania in the Pacific Basin where the action area is located.

Atlantic Ocean

In the western Atlantic, the largest hawksbill nesting population occurs on the Yucatán Peninsula of Mexico. Nesting also occurs in Antigua, Barbados, Costa Rica, Cuba, and Jamaica. Within the U.S., nesting occurs in Puerto Rico, the U.S. Virgin Islands, and along the southeast coast of Florida. At the two principal nesting beaches in the U.S. Caribbean where long-term monitoring has been carried out, populations appear to be increasing (Mona Island, Puerto Rico) or stable (Buck Island Reef National Monument, St. Croix, USVI) (NMFS and USFWS 2007b).

Indian Ocean

Of the approximately 83 nesting rookeries that have been identified for hawksbill sea turtles, 31 occur in the Indian Ocean. Many of those nesting areas are relatively small hosting 100 or fewer nesting females annually. However, some nesting rookeries in Madagascar, Iran, and Western Australia may have as many as 1,000 to 2,000 nesting females annually. Based on the number of nesting females the population trends at the 31 nesting rookeries over the recent past (last 20 years) have remained stable in two locations, declined at five, and are unknown for 24. Historically (20 to 100 years ago), population trends at these nesting rookeries were in decline at 17 sites and are unknown for 14 (NMFS and USFWS 2007b).

Pacific Ocean

Hawksbill turtles nest broadly in the Pacific, including on the islands and mainland of Southeast Asia, from China to Japan, and throughout the Philippines, Malaysia, Indonesia, Papua New Guinea (PNG), the Solomon Islands, and Australia, with the largest nesting concentration occurring on remote islands in the GBR area. However, along the eastern Pacific Rim where nesting was common in the 1930s, hawksbills are now rare or absent (NMFS and USFWS 2007b). Unlike green turtles, hawksbills are solitary nesters, hampering data collection on nesting female numbers, thus all nesting numbers cited below are rough estimates. Hawksbill

nesting information is available for eight locations within Oceania: GBR, PNG, Solomon Islands, Vanuatu, Fiji, Micronesia (Federated States of Micronesia (FSM) and Palau), the Samoan Islands (Western Samoa and American Samoa), and the Mariana Islands. Hawksbill nesting may occur elsewhere within the range of this population, but little to no information is available, and nesting activity at those sites is thought to be very low. Based on the best information currently available, about 5,400 to 6,100 hawksbill turtles nest annually in Oceania, (NMFS 2010a) and the overall trend is downward (NMFS & USFWS 2007b).

Mariana Archipelago

Sub-adult and adult hawksbill turtles occur in low abundance in nearshore waters around the Mariana Islands (NMFS & USFWS 2007b). In CNMI, they have been sighted as far north as Anatahan (Ilo *et al.* 2005) and sporadically around Farallon de Medinilla (Kolinski *et al*. 2004; Ilo and Manglona 2001). They are occasionally observed by divers in the waters of Saipan, and two hawksbills were captured there in 2009 during the in-water monitoring program (CNMI DFW 2009). Hawksbills are also infrequently sighted around Rota (Kolinski *et al*. 2004; Ilo *et al.* 2005). No nesting trend data are available for the CNMI. Although anecdotal information suggests that hawksbill nesting occurred in the CNMI in the past, no nesting activity has been documented in recent years (CNMI DFW unpublished annual reports to PIRO).

Grimm and Farley (2008) report that hawksbills are frequently sighted in the nearshore waters surrounding Guam. However, they are less common than green sea turtles (NMFS and USFWS 2007b). According to Wiles *et al.* (1995), as reported in the BA, hawksbills represent about 13% of turtles sighted around Guam. Based on this and the estimated 150 to 250 green turtles present, NMFS estimates that about 22 to 37 hawksbills reside year-round in the nearshore waters around Guam. Between 5 and 10 hawksbills are estimated to nest annually at Guam, and although trend data are lacking, the population is thought to be declining (NMFS & USFWS 2007b). The first reported hawksbill turtle nest on Guam was in November 1991 (NMFS-USFWS 1998) and in 1997 a possible hawksbill nest was reported from a beach at Sumay Cove (Grimm and Farley 2008). In 2008, four nesting attempts at Adotgan Dikiki (Spanish Steps) were attributed to a hawksbill turtle (Grimm and Farley 2008).

As described above for green sea turtles, information is currently inadequate to comprehensively identify hawksbill turtle in-water habitat around Guam. Although hawksbill habitat needs are somewhat different than greens, significantly in that hawksbills forage heavily on sponges, whereas greens forage primarily on algae and seagrass, it is believed that hawksbill habitat would be similarly included within the area described above as green turtle in-water habitat. As such, hawksbill turtle in-water habitat would be found within the same area outlined above. Thus, for the purposes of this consultation, NMFS is defining hawksbill turtle in-water habitat as that area around Guam found between the shoreline and the 100-foot depth curve including Apra Harbor and the Cocos Island lagoon, an area of 23,000 acres.

3.2.2 Life History Characteristics Affecting Vulnerability to Proposed Action

As with green turtles, hawksbills hatch at their natal beaches, hatchlings spend several years of early development in the oceanic (pelagic) zone. At about 35 cm carapace length, juveniles recruit to coastal areas where post-recruitment juveniles and adults forage and mature in shallow coastal areas, feeding primarily on sponges, but also on other benthic invertebrates, coral, and

algae. When on their foraging grounds, post-recruitment hawksbill turtles are often referred to as "residents". The majority of sea turtles in coastal areas spend their time at depths <5 m below the surface (Schofield *et al.* 2010, Hazel *et al.* 2009). Upon reaching sexual maturity, adult hawksbills typically undertake long migrations between their resident foraging grounds and their natal nesting areas, where they mate and females nest. As with greens, nesting females are referred to as "nesters", which distinguishes them from "resident" turtles that regularly forage in that area. Although males also make mating migrations, because they do not crawl out on the beach as the females do, those males are nearly impossible to distinguish from the resident males.

As with green turtles, hawksbill forage grounds and natal nesting areas are frequently located in different island groups, and residents at a given island group may originate from multiple natal nesting areas. Thus, upon maturation, adult hawksbills undertake long migrations between their resident foraging grounds and their natal nesting areas (NMFS & USFWS 2007b). Two post-nesting hawksbills were fitted with satellite tags on Tutuila; one migrated several hundred km to Western Samoa, and the other migrated more than 1,000 km to the Cook Islands (Tagarino *et al*. 2008). Post-nesting hawksbills on the GBR are reported to migrate more than 2,000 km (Miller *et al*. 1998).

Research into turtle hearing is limited, and no specific information is available for hawksbills. However, based on the similarity in hearing between greens and loggerheads, and the hawksbill's close taxonomic relationship to these species, NMFS considers it likely that hawksbill hearing is also similarly specialized for low frequencies. As described above, green turtles are thought to be most acoustically sensitive between 200 and 700 Hz (Ridgway *et al* 1969). Loggerhead (*Caretta carreta*) hearing is very similar to that of greens, being most sensitive between 250 and 1,000 Hz (Bartol *et al*. 1999). Because the hearing range of hawksbill sea turtles likely overlaps with the expected frequency range of the pile driving signals, NMFS considers it likely that hawksbills can hear, and respond to pile driving noise. Existing information about sea turtle sensory biology also suggests that sea turtles rely more heavily on visual cues, rather than auditory, to initiate threat avoidance, and that they can not be expected to consistently notice and avoid vessels that are traveling faster than 2 knots (kts) (Hazel *et al*. 2007). Consequently, it is likely that hawksbill turtles would be at increased risk of vessel collision due to the expected increased vessel activity.

Hawksbills are thought to occupy a range of habitats including coral reefs or other hard-bottom habitats, sea grass, algal beds, mangrove bays and creeks, or mud flats (NMFS and USFWS 2007b). Post-recruitment juvenile and adult hawksbill turtles were originally thought to forage almost exclusively on sponges (Meylan 1988), however they are known to have a broader diet, consuming zooanthids, soft corals, corallimorphs, ascidians, mobile invertebrates, and polyps of hard corals (Leon and Bjorndal 2002, Obura *et al.* 2010). Survey data for the proposed dredging area in the outer harbor confirm the presence of this habitat as well as numerous species of sponge and coral that may be potential forage resources for hawksbill turtles. Thus, it is reasonable to assume that hawksbills may utilize the area to some degree.

Studies show that sea turtles are adapted for bright light vision and they can see UV wavelengths (Fritsches and Warrant 2006). Although sea turtle and human vision overlaps in the visible light

spectrum, violet and near-UV light sources appear brighter to turtles than to humans (Witherington & Martin 1996). Consequently, sea turtles are most attracted to shorter wavelength lights such as UV, violet, blue, and green (Witherington & Martin 1996), and less attracted to longer wavelength lights, such as yellow, amber, and red. However, it is important to add that intensity is also important; the higher the intensity, the more attractive the light. So, even longer wavelengths can be attractive when at high intensity. Sea turtle hatchlings possess an inborn tendency to move in the direction of the brightest light. Under natural conditions, starlight and moonlight brightens the sky and ocean, drawing the newly emerged hatchlings toward the sea. However, if artificial light sources are present, hatchlings often crawl toward those lights and are led away from the ocean (Witherington and Martin 1996). Artificial light on the beach may also discourage adult females from nesting (Mortimer 1983).

Based on the description of the proposed action and on hawksbill turtle life history characteristics, post-recruitment juvenile and adult hawksbill turtles sheltering and foraging in Apra Harbor are the life stages most likely to be affected by the expected high intensity noise (pile driving) and loss of forage and sheltering habitat (dredging). Post-recruitment juveniles and adults in the nearshore waters in Apra Harbor and are the life stages most likely to be affected by the increased boating activity around Guam. Because the hawksbill turtles found around Guam are likely to migrate widely between their preferred forage and nesting areas, the proposed action may affect hawksbills from multiple NAs across a broad area of the south and western Pacific.

3.2.3 Threats to the Species

Global threats to turtles are described in the 5-year review. As discussed for green turtles (Section 3.1.3), destruction and alteration of habitat, as well as direct harvest are considered the major threats to hawksbills. Climate change also appears to be a growing threat. Destruction and alteration of hawksbill nesting and foraging habitats is occurring throughout the species' global range, especially through coastal development, beach armoring, beachfront lighting, vehicular/ pedestrian traffic, invasive species, and pollution from discharges and runoff. The adverse impacts of these threats described for greens, are virtually the same for hawksbills (NMFS & USFWS 2007b), so they are not repeated here. Although hawksbills interact with some fisheries, their bycatch rates are much lower than for the other sea turtle species, particularly with industrial fisheries.

Harvest of hawksbill shells and eggs continues to be a major threat. Due to the beauty of their shells, hawksbill adults may be harvested more heavily than other sea turtle species. Despite protections under CITES, the "tortoiseshell" trade continues in many areas. As with other sea turtle species, egg harvest continues unabated in parts of the Pacific, including Southeast Asia, Melanesia, and Polynesia (NMFS & USFWS 2007b). Kinch (2007) estimates that approximately 250 hawksbill turtles are sold annually in Port Moresby, but this may represent only a small fraction of the overall subsistence and semi-commercial take of hawksbills in PNG. It is estimated that large numbers of hawksbill turtles from Australian rookeries are being harvested in neighboring countries including Indonesia, PNG, Solomon Islands and Fiji to supply meat and/or tortoiseshell for use locally or for export.

Although hawksbill turtles are probably already being affected by impacts associated with anthropogenic climate change in several ways (described in more detail in the Environmental

Baseline section below), no significant climate change-related impacts to hawksbill turtle populations have been observed to date. However, over the long-term, climate change-related impacts will likely influence biological trajectories in the future on a century scale (Paremsan and Yohe 2003). In the future, climate change-related increasing temperatures, sea level rise, changes in ocean productivity, and increased frequency of storms events are all potential threats to hawksbills for the same reasons described above for green turtles. Additionally, because hawksbills typically inhabit coral reef communities, they are vulnerable to changes that affect these communities, such as increased bleaching events, increased occurrence of disease, and weakening of coral skeletons that may result from global climate change (McWilliams *et al* 2005; Langdon *et al* 2000; Ohde and Hossain 2004). As with green turtles, only limited data are available on past trends, and current scientific methods are not able to reliably predict the future magnitude of climate change and associated impacts or the adaptive capacity of this species. Due to a lack of scientific data, the specific future effects climate change will have on this species are not predictable or quantifiable to any degree that would allow for more detailed analysis in this consultation (Hawkes *et al* 2009). Because of this uncertainty, climate change-related impacts are not considered significant within the context of the temporal scale of this action, as discussed further in the Environmental Baseline and Cumulative Effects sections below.

3.2.4 Conservation of the Species

Numerous conservation programs are being implemented around the world to protect nesting habitat and reduce harvesting and fisheries bycatch of all sea turtle species, and numerous regulatory mechanisms are in place at international, regional, national and local levels to protect sea turtles (Section 3.1.4 above). Many of these programs likely benefit hawksbills. However, hawksbills continue to decline rapidly in the Pacific and Indian Ocean areas (NMFS & USFWS 2007b).

4 Environmental Baseline

The environmental baseline for a biological opinion includes: past and present impacts of all State, Federal, or private actions and activities in the action area; the anticipated impacts of all proposed Federal projects in the action area that have already undergone Section 7 consultation; and the impact of State or private actions which are contemporaneous with the consultation in process (50 CFR 402.02). The Consultation Handbook further clarifies that the environmental baseline is an analysis of the effects of past and ongoing human and natural factors leading to the current status of the species, its habitat (including designated critical habitat), and ecosystem, within the action area (USFWS & NMFS 1998). The purpose of describing the environmental baseline in this manner within a biological opinion is to provide the context for the effects of the proposed action on the listed species. The past and present impacts of human and natural factors leading to the status of green and hawksbill sea turtles within the action area include coastal development, fishing interactions, vessel strikes, direct take, pollution, entanglement in marine debris, and climate change. As described in Section 2 above, the action area for this consultation consist of the nearshore waters within 5 miles around Guam, including Apra Harbor; the USEPA ODMDS if used, including the in-water around tugs and scows as they transit between Apra Harbor and the ODMDS (Figure 1); and the marine waters around military and commercial vessels traveling to and from Apra Harbor due to the proposed action.

Guam is a small tropical island of volcanic origin that is surrounded by coral reefs. It is the southernmost island in the Marianas, and with a land area of 210 miles^2 (544 km^2), it is also the largest. The island is about 30 miles (48 km) long, with about 78 miles (125.5 km) of shoreline. The northern third of the island consists of a relatively flat coralline limestone plateau with steep coastal cliffs and narrow coastal plains. Low hills in the center, give way to mountains in south, where the highest point, 1,332 ft (406 m) Mt Lamlam is located. The island's population was estimated at 178,430 in 2009, and based on an expected growth rate of 1.365% (CIA 2010) is now likely to be about 181,000.

Portions of the nearshore marine environment around Guam have been degraded by impacts from: intense combat during World War II (WWII); shoreline development; sediment-laden runoff; and pollution from run-off and years of poorly treated wastewater effluent. Apra Harbor is a natural deep-water harbor, which has been heavily modified, particularly since World War II (Figure 3).

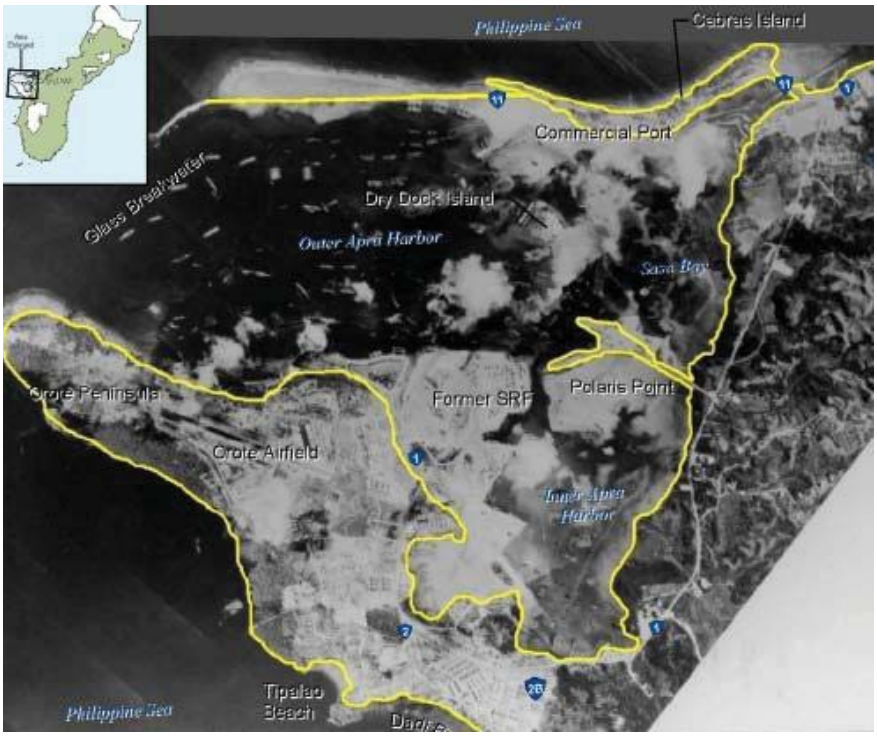

Figure 3. Apra Harbor July 1945. The yellow line indicates the approximate shoreline prior to the dredging and fill projects of the 1940s (USN 2010a).

Much of the harbor's current topography and bathymetry is manmade; the result of work begun by the US Government in 1943. Extensive dredging and fill projects resulted in the creation of Inner Apra Harbor and its channel. Other fill projects resulted in the creation of Dry Dock Peninsula, Polaris Point, and the manmade northeastern and southeastern shorelines, and the Glass Breakwater, which extends from Cabras Island, out and across Luminau Reef to provide increased protection for the harbor. Other impacts include the knolls (hard bottom sites that protrude at least 25 ft (7.6 m) above the harbor bottom) that were explosively cleared during WWII, because they were considered navigational hazards. Some of the shallower knolls have been used as anchorage sites since WWII, and some are still used by military and commercial vessels. Sunken ships rest on the sea floor at several locations throughout the harbor, as does metallic wreckage and other debris. The east end of Apra Harbor is highly developed and brightly illuminated at night. As viewed from Spanish Steps, which is located approximately 4,600 meters west of Polaris Point, industrial facilities light-up a broad swath across the east end of the harbor; with the commercial port and Cabras Island power plant area on the north side, the Naval Station to the south, and

some residential lighting also visible on the hills between (USN 2010d). The existing lights from the commercial port are particularly bright and clearly visible to nesting turtles and hatchlings in the water, and on the beach, at Spanish Steps. The lights of the Naval Station are not quite as bright, but some areas are also clearly visible. It is probable that existing harbor lighting is currently having adverse impacts on green and hawksbill reproductive success at Spanish Steps. Based on the current level of lighting and on the available nesting information, up to 4 adult green turtles and up to 2 adult hawksbill turtles may annually experience some level of light-induced nesting deterrence, and that up to 1,500 green turtle hatchling and up to 750 hawksbill turtle hatchlings may experience increased risk of predation, collision, and exhaustion due to being initially drawn away from the harbor mouth by the artificial lights at the east end of the harbor.

Based on information presented in the Navy's BA, Apra Harbor's turtle habitats and turtle presence can be described as a continuum. The eastern end of the harbor, including the areas proposed for dredging and the CVN wharf area is highly disturbed. Although corals, algae, and sponges, including potential turtle forage are found in the area, benthic resources typically increase in number, size, and diversity as one travels from east to west. Data is limited, but turtle sightings also appear to tend to increase along the same continuum, with turtles being rare in the inner harbor, occasionally present east of Big Blue and Western Shoals including in the area proposed for the CVN wharf and turning basin. Turtles appear to occur in low numbers but are frequently seen on the west sides of these shoals, and they appear to become increasingly common toward the mouth of the harbor, where low-level green turtle nesting continues on the beaches below Spanish Steps, and hawksbill crawls have recently been observed. Low numbers of turtles are also observed in Sasa Bay, east to northeast of Polaris Point, where sponges, macro algae, and sea grass provide forage resources.

Nearshore fisheries on Guam consist primarily of subsistence fishing, but there are also small-scale commercial fisheries for coral reef and pelagic species. Contemporary methods include: boat-based and land-based hook-and-line fishing (handline or rod-and-reel), net fishing (cast, gill, drag, and surround net), spear fishing, hook and gaff, and gleaning (Hensley and Sherwood 1993). Nearshore fisheries occasionally result in entanglement and drowning of sea turtles. Gillnets are the most problematic for turtles, because the nets are left untended, and entangled animals usually drown. Hook-and-line fishing also hooks or entangles turtles, but the chance of survival is higher than if caught in a gillnet. In a study of stranded green turtles in Hawaii (stranded turtles are injured, sick, or dead turtles found on shore), the most common known cause of stranding was the tumor-forming disease, fibropapillomatosis (28%) followed by hook-and-line fishing gear-induced trauma (7%) and gillnet fishing gear-induced trauma (5%) (Chaloupka *et al*. 2008b). However, most turtles drowned in fishing gear probably sink rather than strand, making it very difficult to estimate the total number of green turtles killed annually by nearshore fishing interactions, even in Hawaii where green turtles are much better monitored and studied than in the Marianas (NMFS 2008).

Hazel *et al*. (2007) report that vessel collision is a significant source of anthropogenic mortality for marine turtles. Based on Hawaii data for the period of 1998 to 2007 (NMFS 2008), the estimated total number of green turtles killed annually by boat collisions in the Main Hawaiian Islands (MHI) was between 25 and 50. The number of hawksbills similarly killed was much lower; between 0.2 and 0.4 turtles annually. The nearshore densities of boats and turtles are

much lower around Guam than in Hawaiian nearshore waters, thus the number of green and hawksbill turtles killed annually by boat collisions around Guam is likely much lower. Although little information exists to quantify this impact, vessel collision has been implicated as the cause of three green turtle strandings in Apra Harbor between November 2002 and April 2008 (DAWR unpublished data), suggesting that about three green turtles may be struck by vessels annually.

Other impacts on green and hawksbill turtle environmental baselines within the action area include continued illegal harvest, marine debris, contaminants, and climate change. Direct take through harvest of turtles and their nest continues on Guam and the other inhabited islands of the Mariana Archipelago, however, few data are available to quantify this impact. Vogt (2009) reported obvious poaching activity of nests on Tinian during surveys in 2007. During the 2009 nesting season on Saipan, three out of what is thought to be a total of five nesting turtles were poached as were three nests (DFW 2009). On Guam, DAWR has responded to 17 poachings of greens and 1 hawksbill since 1975 (S. Wusstig personal comm.) On a positive note, some of those 18 animals were rescued alive and released, including the hawksbill.

In addition to the effects of sediment-laden and polluted runoff, Guam's nearshore waters have been impacted by years of poorly treated wastewater effluent discharges around the island. In 1986, the US Environmental Protection Agency (USEPA) issued permits, under the National Pollutant Discharge Elimination System (NPDES), that allowed Guam Waterworks Authority (GWA) to discharge wastewater effluent into the nearshore marine environment following primary treatment of wastewater. Primary treatment follows coarse screening and grit settlement, and removes only about 60% of the suspended solids in the wastewater by allowing the water to rest in settlement tanks that are used to remove material that floats or settles out (Mancl 1996, USGS 2010). Following that, chlorination is normally employed to reduce pathogens. However, the NPDES permits expired in 1991 and were not reissued due to GWA's inability to meet the required standards (US District Court 2003). Additionally, the action area may be suffering impacts from thermal discharges from power plants.

Marine debris continues to accumulate in the ocean and along shorelines within the action area. Turtles may become entangled and drown, and ingested trash may cause intestinal blockage and death. Between October 2004 and September 2008, the American Samoa Department of Marine and Wildlife Resources (DMWR) necropsied 4 green turtles that stranded on Tutuila. Of those 4, 2 had plastic and aluminum in their guts (Tagarino *et al*. 2008). However, because only a small percent of dead or dying sea turtles strand, little information is available to adequately quantify the impacts on green and hawksbill turtles that may result from climate change, marine debris, and contaminants in the action area. Accumulated marine debris on nesting beaches can also impede nesting success by altering nest excavation and through potential entrapment of hatchlings under debris that is inadvertently buried over them when the nesting female covers the clutch. The nesting beaches Spanish Steps are heavily impacted by accumulated marine debris and non-native plants.

The global mean temperature has risen 0.76°C over the last 150 years, and the linear trend over the last 50 years is nearly twice that for the last 100 years (Solomon *et al* [eds] 2007). Because climate change is a global phenomenon, resultant impacts have likely been occurring in the action area although scientific data describing any impacts that have occurred from climate

change in the action area are lacking. As discussed in the Threats Section, climate change is likely beginning to affect sea turtles found in the action area through the impacts of rising sand temperatures, rising sea level, increased typhoon frequency, and changes in ocean temperature and chemistry.

While sex ratios vary naturally within and among seasons and nesting locations, several species already exhibit female bias throughout their major rookeries worldwide (Chan and Liew 1995; Godfrey *et al* 1996; Marcovaldi *et al* 1997; Binckley *et al* 1998; Godfrey *et al* 1999; Godley *et al* 2001; Oz *et al* 2004; Kaska *et al* 2006). Monitoring data over a long enough timescale to discern climate change related trends in sex ratio have not been collected in the action area. Sea level rose approximately 17 cm during the 20th century (Solomon *et al* [eds] 2007) and further increases are expected. There are several predictions for potential future sea turtle nesting habitat loss due to sea level rise (Fish *et al* 2005; Baker *et al* 2006; Fuentes *et al* 2009), however available data are insufficient to determine an existing correlation between past sea level rise and sea turtle population dynamics (VanHoutan 2010).

Global climate change-induced elevated temperatures, altered oceanic chemistry, and rising sea level may be contributing to changes to coral reef and seagrass ecosystems (as described above in Status of the Species) which provide resting and foraging habitat for green and hawksbill sea turtles, although it is difficult to distinguish impacts of climate-related stresses from other stresses that produce more prominent short term effects (Parry *et al* [eds] 2007). Climate change-induced shifts in ocean productivity linked to temperature changes (Harwood 2001; Edwards & Richardson 2004; Hays *et al* 2005) may affect foraging strategies and therefore reproductive capacity for sea turtles (Solow *et al* 2002; Chaloupka *et al* 2008), similar to what has been observed during El Nino events in the Pacific (Limpus and Nicholls 1994; Chaloupka 2001; Saba *et al* 2007; Reina *et al* 2008). These shifts in abundance of foraging resources are also directly linked to observed modifications in phenology for sea turtles such as longer re-migration intervals and temporal shifts in nesting activity (Weishampel *et al* 2004; Hawkes *et al* 2007). However, at this time it is only possible to speculate as to the implications of such impacts, as findings raise numerous follow up questions (listed by Weishampel *et al* 2004) including whether earlier nesting will affect overall fecundity, clutch size, incubation length, hatch success, hatchling survivorship, food availability for hatchlings, mating synchrony, and sex ratio. Changes in reproductive capacity and temporal shifts of nesting activity associated with changing environmental conditions have not been studied specifically in the action area.

Additional potential effects of climate change on sea turtles include range expansion and changes in migration routes (Robinson *et al* 2008). Leatherbacks have extended their range in the Atlantic north by 330km in the last 17 years as warming has caused the northerly migration of the 15°C SST isotherm, the lower limit of thermal tolerance for leatherbacks (McMahon and Hays 2006). Similar studies have not been done for the green and hawksbill sea turtles that may be adversely affected in the action area. As such, scientific data are lacking on changes in migration routes of these sea turtles. Therefore, it is not possible to say with any degree of certainty whether and how their migration routes and ranges have been or are currently being affected.

Causal attribution of recent biological trends to climate change is complicated because non-climatic influences dominate local, short-term biological changes. However, the meta-analyses

of 334 species and the global analyses of 1,570 species show highly significant, nonrandom patterns of change in accord with observed climate warming in the twentieth century. In other words, it appears that these trends are being influenced by climate change-related phenomena, rather than being explained by natural variability or other factors (Parmesan & Yohe 2003). The details discussed previously in this section support the probability that recently observed changes in sea turtle phenology, sex ratio, and foraging characteristics in studied populations may be influenced by climate change-related phenomena. However, the implications of these changes are not clear in terms of population level impacts, and data specific to the action area are lacking. Therefore, as stated earlier, recent impacts from climate change in the action area are believed to be insignificant at this time.

5 Effects of the Action

In this section of a biological opinion, NMFS assesses the probable effects of the proposed action on threatened and endangered species. Effects of the Action refers to the direct and indirect effects of an action on the species or critical habitat, together with the effects of other activities that are interrelated or interdependent with that action that would be added to the environmental baseline. Indirect effects are those that are likely to occur later in time (50 CFR 402.02). The effects of the action are considered within the context of the Status of Listed Species and Environmental Baseline sections of this Opinion to determine if the proposed action can be expected to have direct or indirect effects on threatened and endangered species that appreciably reduce their likelihood of surviving and recovering in the wild by reducing their reproduction, numbers, or distribution (50 CFR 402.02), otherwise known as the jeopardy determination.

Approach. NMFS determines the effects of the action using a sequence of steps. The first step identifies potential stressors associated with the proposed action with regard to listed species. NMFS may determine that some potential stressors result in insignificant, discountable, or beneficial effects to listed species, in which case these potential stressors are considered not likely to adversely affect listed species, and subsequently are considered no further in the opinion. Those stressors that are expected to result in significant negative (i.e., adverse) effects to listed species are analyzed via the second, third, and fourth steps described below.

The second step identifies the magnitude of the stressors (e.g., how many individuals of a listed species would be exposed to the stressors; *exposure analysis*). In this step of our analysis, we try to identify the number, age (or life stage), and gender of the individuals that are likely to be exposed to a proposed action's effects, and the populations or subpopulations those individuals represent.

The third step describes how the exposed individuals are likely to respond to the stressors (*response analysis*). In this step, NMFS determines if the stressors are likely to result in any of the components of take as defined under the ESA (e.g., harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect or attempt to engage in any such conduct).

The final step in determining the effects of the action is establishing the risks those responses pose to listed resources (*risk analysis*). The risk analysis is different for listed species and designated critical habitat. However, the action area does not include proposed or designated critical habitat, thus it is not considered in this opinion. Our jeopardy determinations must be

based on an action's effects on the continued existence of threatened or endangered species as those "species" have been listed, which can include true biological species, subspecies, or distinct population segments of vertebrate species. Because the continued existence of listed species depends on the fate of the populations that comprise them, the viability (probability of extinction or probability of persistence) of listed species depends on the viability of their populations. Thus, because green and hawksbill turtles are globally listed, and these species consist of nesting aggregations, this final step first determines the risk posed by the proposed action to affected nesting aggregations, then relates that risk to the listed species.

5.1 Stressors

The following 9 potential stressors may occur due to the proposed action: elevated noise levels; loss or degradation of sheltering and forage habitat; vessel collision; direct impact by dredging or chiseling equipment; increased artificial lighting; disturbance from human activity and equipment operation; elevated turbidity; increased wastewater effluent; and increased wastes and discharges. NMFS has reviewed each of the stressors to determine if their effects are expected to be significant (e.g. size of the impact), discountable (how likely it is to occur), or beneficial (positive effect). Those that are insignificant, extremely unlikely to occur, or beneficial will not be discussed further in this opinion.

5.1.1 Elevated Noise Levels during Pile Driving

The proposed action is expected to result in nearly 2 years of high intensity noise due to pile driving, which may adversely affect sea turtles. The noise may drive turtles away from sheltering and foraging habitats located at or near the proposed CVN wharf and turning basin. Such behavioral modification is considered an adverse effect, and is thus addressed below in the exposure-response-risk analyses.

5.1.2 Loss or Degradation of Sheltering and Forage Habitat

Inner Harbor. The inner harbor portion of the proposed action is expected to result in the seaward extension of four contiguous inner harbor wharves outward 10 ft (3 m) from their current facings, along of combined total of 4,839 ft (1,475 m). This would permanently increase the wharf front's marine footprint by about 48,390 ft^2 (4,425 m^2). The action also includes maintenance dredging about 114 acres of seafloor adjacent to Sierra and Tango Wharves, and the construction of two ramps for amphibious landing craft for the laydown area. The potentially affected sea floor consists mainly of sticky, fine sand and silty mud sediments that provide no sheltering habitat, and supports little or no forage (USN 2010e). However, the encrusting macroalgae and sponges growing on the upper halves of the existing wharf facings provide potential forage habitat, and Abo Cove, at the east end of the inner harbor supports a seagrass bed. The proposed wharf extensions would cause the temporary loss of the encrusting algae and sponges, lost behind the new facings. Neither the new facings, nor the dredging, or the ramps should affect the seagrass bed. Because sea turtles are very rare in the inner harbor, any forage in that area is virtually unused by turtles. Based on the expectation that the sheltering and forage habitat in the inner harbor is both limited and virtually unused, and that any forage losses would be temporary (until marine fouling organisms colonize the new wharf facings and the new ramps), the loss or degradation of sheltering and forage habitat in the inner harbor is expected to have insignificant impacts on sea turtles, and it will be discussed no further in this opinion.

Outer Harbor. The outer harbor portion of the proposed action includes a large dredging footprint that would impact coral reef areas that provide potential turtle forage and sheltering habitat in an area where turtles are known to occur. The outer harbor where the dredging would occur consists of previously-dredged reefs and soft sediment areas, and large flat-topped reefs occur adjacent to this area. The proposed dredging would take place in an area that has been heavily impacted by previous dredge and fill projects, blasting, and on-going anchoring. Despite the area's history of disturbance, some areas of relatively steep sloped hard substrate with overhangs and other openings that may provide turtle sheltering habitat still exist in the proposed dredging area. However, this habitat type was not specifically surveyed or quantified. The area also supports diverse marine life, including sponge and algae that may provide forage resources for green and hawksbill turtles, and low numbers of turtles have been observed in and around the area. The expected loss or degradation of this habitat would result in the permanent loss or degradation of turtle foraging and sheltering resources. These resource losses are considered an adverse effect, and are thus addressed below in the exposure-response-risk analyses.

5.1.3 Vessel Effects

The proposed action is expected to result in increased military and commercial vessel traffic entering Apra Harbor, and the proposed dredging is expected result in tug and scow trips to the ODMDS. As described in the FEIS, the proposed action is expected to result in 1 additional CSG visit (about 9 large vessels per CSG), and up to 4 additional ATF visits (about 7 large vessels per ATF). About 15 Amphibious Assault Vessel (AAV) trips and up to 20 Landing Craft Air Cushion (LCAC) trips are also expected per ATF visit. This totals 177 additional military trips annually. The FEIS also reported that 362 additional commercial vessel trips are expected during the 2015 construction peak, after which NMFS expects commercial shipping to drop to about 79 arrivals above 14-year average. About 234 tug and scow trips to the ODMDS would be expected should all dredged material be disposed at the ODMDS. The FEIS reported that those trips would occur at a rate of about 1 to 2 per day during the proposed dredging. It is doubtful that the maximum number of military vessels would visit before harbor construction was complete, but if that were to happen, the maximum number of military vessels plus the maximum number of additional commercial vessels plus all of the tug and scow trips combined would total about 773 trips annually. This maximum number is unlikely to occur, and could only conceivably occur during the year of the construction-related peak commercial traffic while dredging was being done. Annual additional traffic would likely be much lower during the construction period, and the additional post-construction vessel traffic would be about 256 trips for military and commercial combined. Apra Harbor operating rules restrict vessel speeds to 12 nautical miles per hour (kts), or less in the outer harbor, and 5 kts or less in the inner harbor (NOS 2010). The large vessels would transit the harbor via established channels that take advantage of the deepest available waters. Based on the low number of these trips, the expected low speeds, and the expectation that in-harbor turtle density is lowest in the channels, NMFS has determined that the potential for additional military or commercial vessels to collide with sea turtles is discountable and this stressor will be discussed no further in this opinion.

5.1.4 Direct Impact by Dredging or Chiseling Equipment

Sea turtles could conceivably be struck by the digging bucket or the drop chisel if they were below either of those pieces of equipment. Potential injuries and their severity would depend on the animal's proximity to the bottom when struck, the angle of the strike, and the body part

impacted. Injuries may include cuts, bruises, broken bones, cracked or crushed carapaces, and amputations, any of which could result in the animal's death. However, clamshell dredging, including the use of a drop chisel, is a relatively stationary activity that impacts very small areas at any given time. Sea turtles must be directly beneath the bucket or chisel in order to be injured or killed by this type of dredging. Also: few sea turtles are expected to be in the dredging area; the applicant has committed to watch for turtles starting 60 minutes prior to commencing dredging or chiseling operations, with work being postponed or halted when turtles are within 50 yards; and the contractor must initiate all dredging/chiseling operations employing a soft start, whereby the dredge or chisel would be slowly lowered to the bottom for the first few drops. The soft start is expected to alert undetected marine animals and allow them time to depart the area before full impact operations begin. Based on implementation of these practices and considering information that sea turtles are likely to depart or avoid areas where dredges and drop chisels are used, we have determined that the likelihood of a sea turtle being adversely injured or killed by clamshell dredging or chiseling is discountable, and this stressor will be discussed no further in this opinion.

5.1.5 Increased Artificial Lighting

Several components of the proposed action include the installation of an undetermined number of tall light poles with 1,000 watt lights in the vicinity of the shore line in the inner harbor and at Polaris Point. The precise number of light poles is expected to vary based upon on-site requirements, but many are expected to replace existing light fixtures. The proposed action also includes 18 months of around-the-clock dredging off of Polaris Point. Lighting from the proposed new construction at Polaris Point, as well as the illuminated dredging barge would be within line-of-sight from the nearshore waters at Spanish Steps. The proposed dredging area is between 3,600 and 4,600 meters east of Spanish Steps. The proposed lights have the potential to deter or disorient nesting green and hawksbills and their hatchlings in the marine waters at Spanish Steps. However, as described in the FEIS, and noted above, many of the lights to be installed at the Naval Station would replace existing fixtures. In addition, the Navy's mitigation measures for artificial lighting require that lighting systems be designed to meet minimum safety and security standards, and to the maximum extent practicable employ hooded lights for construction near turtle terrestrial habitats (USN 2010e).

NMFS is aware of no scientific studies that measure or assess the artificial lighting that is currently visible from Spanish Steps. In addition, there are no current studies that quantify or evaluate the impacts that illumination may be having on the nesters and hatchlings at that particular nesting beach. However, as described in the Environmental Baseline Section, the east end of Apra Harbor is an industrial area that is already brightly illuminated at night across a wide swath. Given the existing lighting in this industrial area, the distance of the dredging site from Spanish Steps, the limited scope of the project area that would be visible from Spanish Steps, and the expected use of mitigation measures to reduce horizontal light transmission to the maximum extent practicable, NMFS considers it likely that any additional illumination from the proposed action would be barely detectable above the existing lighting levels at the Naval Station. Accordingly, NMFS expects that the proposed action would result in no significant increase in illumination at or near the nesting beaches at Spanish Steps. Consequently, NMFS has determined that the impacts of additional illumination would be insignificant on the affected sea turtles, and this stressor will be discussed no further in this opinion.

5.1.6 Disturbance from Human Activity and Equipment Operation

This stressor refers to construction-related disturbances other than exposure to elevated noise levels. Exposure to construction activities may startle sea turtles should they encounter them. Sea turtle density is considered low in the proposed construction areas, and turtles typically avoid human activity around Guam because they are wary of humans due to continued poaching (S. Wusstig personal comm.). Based on this, the most likely effect of this interaction is a moderate to high energy avoidance behavior leading to the animal rapidly leaving the area without injury. Additionally, the Navy would reduce the likelihood of this interaction by watching for and avoiding sea turtles before commencing work and by postponing or halting operations when protected species are within a minimum of 50 feet of construction activities other than pile driving and dredging, which have protected species safety ranges of 50 m (USN 2010a). Based on the information above, we expect that disturbances from human activity and equipment operation would be infrequent and non-injurious, resulting in insignificant affects on green and hawksbill turtles. As such, this stressor will be discussed no further in this opinion.

5.1.7 Increased Turbidity

Green and hawksbill sea turtles are often found in turbid waters. Since sea turtles breathe air instead of water, exposure to increased turbidity should not adversely affect their respiration or other biological functions. However, turtles may avoid dense turbidity plumes in favor of clearer water. The use of a clamshell bucket to dredge the inner and outer harbors is expected to mobilize bottom sediments and create a plume of suspended solids. The applicant has committed to employing silt curtains around dredging to the greatest extent practicable, but the use of surface-to-bottom curtains is unlikely in some areas. As such, the turbidity plume is expected to extend beyond the dredging footprint, particularly around the CVN turning basin. Although it is impossible to predict how individual animals might react to plumes of elevated turbidity, we expect that a low number of sea turtles may temporarily avoid the dredging area due to turbidity plumes. Avoidance due to turbidity would likely be temporary, and the displacement distance is expected to be short, plus any movement away from the dredging area would have an added benefit of reducing the likelihood of a turtle being injured by dredging. We expect that the impacts of this stressor would be insignificant on the affected sea turtles because aerial avoidance due to turbidity would likely be temporary, the displacement distance is expected to be short, and any movement away from the dredging area would have an added benefit of reducing the likelihood of a turtle being injured by dredging. Based on the expected insignificance of exposure, this stressor will be discussed no further in this opinion.

5.1.8 Increased Wastewater Effluent

The proposed action is expected to result in increased wastewater discharged into the nearshore marine waters around Guam. Most of the increased effluent discharge is expected to occur at the Northern District Wastewater Treatment Plant (NDWTP) where the current design capacity is 12.0 million gallons per day (mgd) average daily flow, and the average daily flow is currently 5.7 mgd. The recently relocated outfall into the ocean is located about 1,900 feet off shore, in about 140 feet of water. This outfall currently discharges without a functioning diffuser due to design problems. According to the FEIS, the proposed action could result in a maximum additional flow from the NDWTP of 6.4 mgd during the 2014 construction peak (12.1 mgd total flow), as well as much smaller increases at other WTPs around the island. The post-construction additional flow at the NDWTP is expected to stabilize at about 4.9 mgd above the current level

(10.6 mgd total). According to the FEIS, the Navy is considering a suite of options including: restoring and expanding the NDWTP's primary treatment capabilities; expanding and upgrading the NDWTP to secondary treatment. However, no commitment of financial or material resources has been made as of this time. The Navy is also considering implementing FFR to ensure that the increased population does not exceed the WTP's capabilities; and implementing their AMP to monitor environmental conditions to minimize adverse impacts from the proposed action.

The limited research available to assess the impacts of the NDWTP on marine resources found no adverse impacts on the health of corals exposed to the effluent (McKenna *et. al.* 2001). Pastorok and Bilyard (1985) suggest that in well-flushed waters along open coasts, sewage effluent has little or no adverse impact on coral reef communities. Additionally, there is no record of fibropapillomatosis (FP) in green turtles from Guam. FP is the only turtle disease currently linked with wastewater effluent (Guimaraes dos Santos *et. al.* 2010). Although the discharged effluent is currently below primary treatment standards, the volume of the maximum expected additional discharge is small. Additionally, the NDWTP discharges into open ocean waters beyond typical green and hawksbill sheltering and foraging habitats, and off the leeward coast, where the prevailing currents are expected to draw the plume away from shore. Based on the Navy's study of this outfall, the effluent rises quickly to the surface with minimal horizontal dispersion in mid-column. At the surface, prevailing winds and currents disperse and dilute the plume. Phytoplankton assimilate nutrients in the existing plume, while zooplankton and small fish graze on the phytoplankton and some of the suspended solids. Based on the expected planktonic trophic interactions, no detectable changes are expected in the standing phytoplanktonic biomass (no expected algal blooms) as a result of the increased effluent discharge. NMFS expects no negative impacts on turtle habitat in the vicinity of the outfall. Based on the best available information: 1) the expected volume of effluent is small, 2) the effluent is discharged beyond typical green and hawksbill nearshore habitat, 3) the plume is expected rise to the surface where it will quickly disperse away from nearshore turtle habitat, and 4) available studies indicate no adverse habitat impacts nor FP due to the outfall; NMFS concludes that the expected increase in wastewater effluent discharge would have insignificant impacts on green and hawksbill turtles. As such, this stressor will be discussed no further in this opinion.

5.1.9 Increased Wastes and Discharges

Construction wastes may include plastic trash and bags that may be ingested and cause digestive blockage or suffocation, or if large enough, along with discarded sections of ropes and lines, may entangle marine life. Equipment spills and discharges likely consist of hydrocarbon-based chemicals such fuel oils, gasoline, lubricants, hydraulic fluids and other toxicants, which could expose protected species to toxic chemicals. Depending on the chemicals and their concentration, the effects of exposure may range between animals temporarily avoiding an area, to death of the exposed animals. Local and Federal regulations prohibit the intentional discharge of toxic wastes and plastics into the marine environment. Additionally, the Navy has incorporated into their proposed action BMPs that include measures intended to prevent the introduction of wastes and toxicants into the marine environment (USN 2010a). Based on the information above, we expect that construction-related discharges and spills would be infrequent, small, and quickly cleaned if they do occur. Therefore, we have determined that exposure to construction-related wastes and

discharges would result in insignificant effects on green and hawksbill turtles, and this stressor will be discussed no further in this opinion.

Stressors Summary. As explained above, 2 of the 9 stressors associated with the proposed action were considered likely to adversely affect green and hawksbill turtles (elevated noise levels, and loss or degradation of sheltering and forage habitat). These stressors are addressed in the exposure-response-risk analyses below. The other 7 stressors (direct impact by dredging or chiseling equipment, increased artificial lighting, disturbance from human activity and equipment operation, elevated turbidity, increased wastewater effluent, and increased wastes and discharges) were determined to be not likely to adversely affect sea turtles and are addressed no further in this opinion.

5.2 Exposure

This section analyzes the proposed action's potential for exposing green and hawksbill sea turtles to the 2 stressors associated with the proposed action that were identified above as likely to result in adverse effects to green and hawksbill turtles: 1) Adverse levels of sound energy during pile driving operations in Apra Harbor and 2) impacts of lost or degraded sheltering and forage habitat due to dredging in outer Apra Harbor.

5.2.1 Exposure to Elevated Noise Levels during Pile Driving

This analysis is based on the piling types, the method of driving, the expected substrate, and the duration of work as described in the March 12, 2010 BA and the FEIS (USN 2010a & e), as well as the expected source levels for similar pile driving actions, based on the California Department of Transportation's Compendium of Pile Driving Sound Data (Compendium) (CALTRANS 2007). The exposure analysis is organized as follows:

1: Estimate the in-water source level for each pile driving project.

2: Estimate the ranges where in-water sound energy would fall to current thresholds for expected effects.

3: Estimate the areal extent of affected habitat where green or hawksbill sea turtles may be potentially exposed to sound energy at or above the threshold adverse affect.

5.2.1.1 Estimate the in-water source level for each pile driving project:

As described in Section 3, the CVN wharf project would require about 2,050 hours of work to impact drive about 410 24-inch (61 cm) wide steel pipe pilings. Assuming 24-hour work days, 7 days a week, the CVN Wharf would require a minimum of about 3 months of pile-driving. Similarly, the inner harbor wharf project would involve up to 18 months of around-the-clock work to impact drive about 1,115 23.6-inch steel sheet pilings and 1,684 36- X 18-inch steel H-piles along 4,840 linear feet (1,475 m) of wharf front.

Acoustics Background. Sound can be measured and quantified in several ways, but the logarithmic decibel (dB) is the most commonly used unit of measure, and sound pressure level (SPL) is a common and convenient term used to describe intensity. In water, sound pressure is typically referenced to a baseline of 1 micropascal (re 1 μPa), vice the 20 μPa baseline used for in-air measurements. Consequently, 26 dB must be added to an in-air measurement to convert to an appropriate in-water value for an identical acoustic source (Bradley and Stern 2008). To assess the potential impact of a sound on marine resources, NMFS often assesses impacts based

on the root-mean-square (dB_{rms}) of an acoustic pulse. This is the portion of a pulse that contains 90% of the sound pressure. For brevity, all further references to SPL assume dB_{rms} re 1 μPa, unless specified differently.

Sound Transmission in Water. Transmission loss (attenuation of sound intensity over distance) varies according to several factors in water, such as water depth, bottom type, sea surface condition, salinity, and the amount of suspended solids in the water. Sound energy dissipates through mechanisms such as spreading, scattering, and absorption (Bradley and Stern 2008). Spreading refers to the apparent decrease in sound energy at any given point on the wave front because the sound energy is spread across an increasing area as the wave front radiates outward from the source. In unbounded homogenous water, sound spreads out spherically, loosing as much as 7 dB with each doubling of range. Toward the other end of the spectrum, sound expands cylindrically when vertically bounded such as by the surface and substrate, losing only about 3 dB with each doubling of range. Scattering refers to the sound energy that leaves the wave front when it "bounces" off of a surface or particles in the water. Absorption refers to the energy that is lost through conversion to heat due to fiction. Irregular substrates, rough surface waters, and particulates in the water column increase scattering loss, while soft substrates, such as mud and silt increase absorption loss. Sound typically dissipates more rapidly in shallow, turbid waters over soft substrates (74 FR 18492). The water of Apra Harbor is expected to be a poor environment for acoustic propagation because it is relatively shallow, with an irregularly shaped bottom and high levels of silt and mud.

Accurately predicting received noise levels at a given range (isopleth) requires complex equations and detailed information that is rarely available. The equation "RL = SL – 20LogR" is used to calculated spherical spreading loss, and "RL = SL – 10LogR" is used for cylindrical spreading (RL = received level; SL = source level; and R = range in meters). Actual spreading loss is typically somewhere between spherical and cylindrical, with absorption and scattering increasing the loss. Consequently, predictions are often made by estimating transmission loss using an equation with a spreading coefficient between -20 and -10. To account for the acoustic environment expected within Apra Harbor, RL = SL – 15LogR was used to calculate estimated transmission loss and estimate ranges to threshold isopleths. Outside of the harbor, the bottom drops away dramatically and transmission loss likely approaches that of spherical spreading.

Pile Driving Noise. The in-water source level (SL) is the sound energy at 1 m from the source. The SL of impact pile driving is typically high, sometimes in excess of 200 dB (CALTRANS 2007). Frequencies vary according to several factors, including the type of piling and substrate as well as the intensity of impact. Signal analysis of sheet piles indicates a relatively broadband signal with most of the energy between 25 and 4,000 Hz. The dominant frequency range for 24-inch steel pipe piles falls between 125 and 2,500 Hz, with a peak at about 375 Hz. H-pile signals were described as "…higher frequency content than steel pipe…", with frequencies above 500 Hz to over 1,000 Hz. SPL is also affected by pile type and the substrate (the harder and larger the piling, the louder; the harder the bottom, the louder), as well as the impact energy (the harder the impact, the louder). Measured SPLs for individual pile driving events may vary over time. Green and hawksbill sea turtles are the only ESA-listed marine animals expected to occur within Apra Harbor where pile driving noise may reach levels capable of causing adverse effects. As described in Section 4, greens and hawksbills are thought to be low frequency specialists, with

hearing ranges that overlap with the expected frequency range of the pile driving signals. Thus, NMFS considers it likely that green and hawksbills can hear, and respond to pile driving noise.

5.2.1.2 Estimate the ranges where in-water sound energy would fall to current threshold for expected effects:

Neither the Navy nor NMFS has site-specific noise measurements for pile-driving in Apra Harbor. Consequently, the Navy and NMFS referred to the CALTRANS Compendium, and other sources cited in the Navy's BA, under the assumption that reported sound levels would closely approximate sound levels expected for similar pilings, driven in a similar manner in Apra Harbor. As described in the BA, impact driving steel sheet piles would be the loudest of the three piling types. Back-calculations with measured levels between 189 and 190 dB at 10 meters (m) suggest a SL of 205 dB (Table 3). Impact driving 24-inch steel pipe piles is expected to produce a SL of 203 dB, while the SL for impact driving 18-inch H-piles is expected to be 195 dB. The mouth of Apra Harbor is about 5,000 m from the nearest proposed pile driving (CVN Pier), where the estimated received sound level drops to 148 dB. As mentioned above, transmission loss outside of the harbor is likely to increase because spreading loss is expected increase due the dramatic increase in water depth.

Table 3. Estimated source levels and ranges to effects threshold isopleths for proposed pile driving types.

Steel Pilings	SL	Range to 180 dB PTS	Range to 160 dB TTS
23.6-in Sheet	205 dB	46 m	1,000 m
24-in Pipe	203 dB	34 m	741 m
18-in H	195 dB	10 m	214 m

Exposure to high intensity noises may adversely affect marine life. Effects vary with the frequency, intensity, and duration of the sound source, and the hearing characteristics of the exposed animal. In extreme cases, exposure to very high levels of sound can cause soft tissue injuries that may directly result in fatality. Exposure to lower levels may cause injury in the form of permanent hearing damage, also referred to as permanent threshold shift (PTS). Exposure to even lower levels may cause behavioral effects that range from temporarily reduced sensitivity also referred to as temporary threshold shifts (TTS), to temporarily masked communications and/or acoustic environmental cues, and areal avoidance. For exposure to sounds in water $\geq$ 180 dB is the threshold for PTS for cetaceans. Exposure to in-water sounds $\geq$ 160 dB is the threshold for TTS for all marine mammals.

Currently, no acoustic thresholds have been established for sea turtles. However, existing research available into sea turtle sensory biology suggests that sea turtles are less acoustically sensitive than cetaceans, relying more heavily on visual cues, rather than auditory input (Hazel, *et al*. 2007, Ridgeway *et al*. 1969). Thus, application of the marine mammal thresholds is considered conservative for sea turtles. Estimating attenuation based on RL = SL - 15logR suggests that the 180 and 160 dB isopleths would occur at ranges of 46 and 1,000 meters, respectively for sheet piles, whereas driving the H-piles would have ranges well within those of the co-located sheet piles (Table 3, and Figure 4). Similarly, the 180 and 160 dB isopleths for driving the pipe piles would occur at ranges of 34 and 741 meters. The estimated received level falls to 148 dB at the mouth of the harbor, at which point the spreading loss is expected to increase. Based on the information above, we expect that adverse levels of sound would be restricted to the area within Apra Harbor, and that at most, exposure of ESA-listed animals to

pile driving noise outside of the harbor may result in low levels of temporarily masked communications or acoustic environmental cues, resulting in insignificant behavioral responses that are likely to range between "awareness" of the noise to low level areal avoidance.

Figure 4. Apra Harbor showing the approximate ranges to the 180 dB (≈50 m) and 160 dB (≈1000 m) isopleths for sheet pile driving (red lines), and to the 180 dB (≈40 m) and 160 dB (≈740 m) isopleths for pipe pile driving (yellow lines).

5.2.1.3 Estimate the areal extent of affected habitat where green or hawksbill sea turtles may be potentially exposed to sound energy at or above the threshold adverse affect:

Available data strongly suggest that low numbers of green and hawksbill sea turtles reside year-round to rest and forage in nearshore waters, and sightings confirm ongoing presence of greens in Apra Harbor, including greens periodically observed on the surface in the area of the proposed CVN turning basin. Low numbers of hawksbills are also expected to occasionally occur in the harbor. Additionally, low level green turtle nesting has been confirmed at the mouth of the harbor at Spanish Steps (USN 2010a). However, current data are insufficient to determine precisely the total number or density of either species around Guam or in Apra Harbor. Although the Navy's BMPs require that pile driving be postponed or halted when turtles are within 100 m, NMFS considers it unlikely that turtles would be consistently detectable in the water at ranges beyond 50 meters. As described above, 46 m is the range at which potentially injurious levels of sound (PTS) are expected to radiate outward from driving sheet pilings, and 34 m is the range for PTS from pipe pilings. Consequently, NMFS expects that no turtles would be exposed to sound levels at or above 180 dB, but pile driving may expose a low but undetermined number of turtles to sound levels at or above 160 dB (TTS threshold) out to about 1,000 m for sheet pilings, and 741 m for pipe pilings (Figure 4). NMFS is currently unable to quantify the number of turtles likely to be adversely affected by this stressor. However, the areal extent of the expected zone of acoustic impact (out to the 160 dB isopleth) encompasses about 747 acres of potential turtle habitat. Based on the estimation that there is about 23,000 acres of potential green and hawksbill turtle habitat around Guam (Section 3 above), 747 acres represents about 3.2% of Guam's available turtle habitat.

5.2.2 Exposure to Loss or Degradation of Sheltering and Forage Habitat

As discussed in Section 5.1.2 the loss or degradation of sheltering and forage habitat in the inner harbor is expected to have insignificant impacts on sea turtles. This analysis assesses the effects the proposed action is expected to have on ESA-listed sea turtles through the loss or degradation of their sheltering and forage resources due to the proposed action in the outer harbor. This analysis is limited strictly to the potential impacts on those species as defined by the ESA, and does not assess habitat quantity or ecosystem functions as may apply to valuation estimates for compensatory mitigation under the National Environmental Policy Act (NEPA) or any other statue. The analysis is based on reported turtle sheltering and forage resources expected to be permanently lost or degraded, or temporarily denied to green and hawksbill sea turtles in outer Apra Harbor, the expected spatial and temporal extent of the habitat impacts, and the number of green and hawksbill sea turtles potentially affected by those habitat impacts. The exposure analysis is organized as follows:

1: Describe the sheltering potential and forage resources within the proposed dredging footprint, and in adjacent areas.
2: Estimate the spatial and temporal extent of directly and indirectly impacted habitats.
3: Estimate the areal extent of lost or degraded green and hawksbill turtle habitat.

5.2.2.1 Describe sheltering potential and forage resources within the proposed dredging footprint, and in adjacent areas:

As described in the Environmental Baseline Section, the proposed dredging would take place in an area that has been heavily impacted by previous dredge and fill projects, blasting, and on-going anchoring. Despite the area's history of disturbance, some areas of relatively steep sloped hard substrate with overhangs and other openings that may provide turtle sheltering habitat still exist in the proposed dredging area. However, this habitat type was not specifically surveyed or quantified. The area supports diverse marine life, including low numbers of turtles.

The DEIS characterized the outer harbor in the vicinity of the proposed dredging area as consisting of three major and eight secondary biotopes. The primary biotopes are: large flat-topped reefs; dredged reefs; and soft sediment areas. The later two are the biotopes found in the proposed dredging area. The large flat-topped reefs are the shoals, such as Big Blue, Jade and Western Shoals that boarder the operational channel and proposed turning basin. Secondary biotopes include "rubble, mud, and sand", which accounts for about 35% of the total dredge footprint; and "algal beds", which accounts for about 40% of the footprint. The remaining 25% is made up of coral "supracolonies", various coral communities, and mixed communities of corals, algae, and sponges. Benthic surveys were conducted to describe the general benthic cover, and to identify algae and sponges present in the area. It did not quantify the abundance of those resources, but described benthic habitat in percentages of the bottom covers by particular organisms. Over 90 algal species and more than 50 species of sponge were identified in the area, with about 10 of the algae identified as known or suspected green turtle forage.

Russell and Balazs (2009) report that green turtles in Kaneohe Bay, Oahu have modified their feeding behavior to include seven nonnative algae that are now growing in the bay. The turtles consumed 130 species of marine vegetation, with the three most commonly consumed being nonnative species, *Acanthophora spicifera, Gracilaria salicornia,* and *Hypnea musciformis,*

(documented in the dredge area). Thus, it must be assumed that green turtles are likely opportunistic feeders, and that turtles in Apra Harbor likely feed on forage resources beyond the known forage species.

Although sponges are adult hawksbill's primary forage resource (Meylan 1988), they are known to have a broader diet, consuming zooanthids, soft corals, corallimorphs, ascidians, mobile invertebrates, and polyps of hard corals (Leon and Bjorndal 2002, Obura *et al.* 2010). Lutz and Musik (1997) suggest that the more juvenile the hawksbill, the more omnivorous the diet, including algae such as *Gracilaria* and *Sargassum spp* (documented in the dredge area), as well as seagrasses, soft corals, tunicates, and bryozoans. The authors also report that gravid females are know to eat *Halimeda spp* (documented in the dredge area), apparently for its calcium to aid production of eggshells. Specific information is lacking to identify forage sponges to genus for Pacific hawksbills, but Lutz and Musik (1997) and Fuentes (2009) report that many sponges of the Class Demospongiae are hawksbill forage. At least nine of the genera identified in the survey belong to the Class Demospongiae. Thus, NMFS considers it likely that at least some of those sponges may be forage resources for hawksbills, as are some of the identified algae.

5.2.2.2 Estimate the spatial and temporal extent of directly and indirectly impacted habitats:

To widen and deepen the operational channel, as well as create the turning basin and prepare the Polaris Point shoreline for the CVN wharf, dredging of about 53 acres, including up to about 33 acres of coral reef habitat would be required. The proposed dredging footprint includes shallow areas southwest of Jade Shoals and northeast to east of Big Blue, including Polaris Point at the entrance to the inner harbor (Figure 5). In addition to the area expected to be directly impacted by the dredging, the Navy has determined that reef habitats extending up to 656 ft (200 m) outward from the dredging area may be impacted by sediment deposition. Based on their plume modeling, the Navy considers the area of indirect impact to be an over-estimate. Dredging is expected to require about 18 months of around-the-clock work to complete.

5.2.2.3 Estimate the areal extent of lost or degraded green and hawksbill turtle habitat:

As described above at 5.2.1.3, green turtles are periodically observed on the surface in the proposed dredging area, and although much less common than greens, hawksbills also occur in the harbor, and are expected to occasionally occur in or near the proposed dredging area. Because data are insufficient to determine the total number or density for either species, NMFS has determined that a low but undetermined number of green and hawksbill sea turtles may be adversely affected by the expected habitat loss and/or degradation due to the proposed dredging. NMFS is currently unable to quantify the number of turtles likely to be adversely affected by this stressor. However, the FEIS estimated that the total impacted area (direct and indirect impacts) would be about 172 acres, which is likely an overestimate due to the need to use -60ft (vice -51ft) for the dredging depth in the Navy's modeling. Assuming that the entire area constitutes green and or hawksbill turtle habitat, this represents about 0.7% of Guam's available turtle habitat. The 53 acres to be dredged represents about 0.2% of potential turtle habitat that would be permanently lost or degraded. The remaining 119 acres of indirectly impacted habitat would represent about 0.5% of potential turtle habitat that would be temporarily degraded by increased sedimentation and mechanical disturbances that would likely induce turtles to avoid the area.

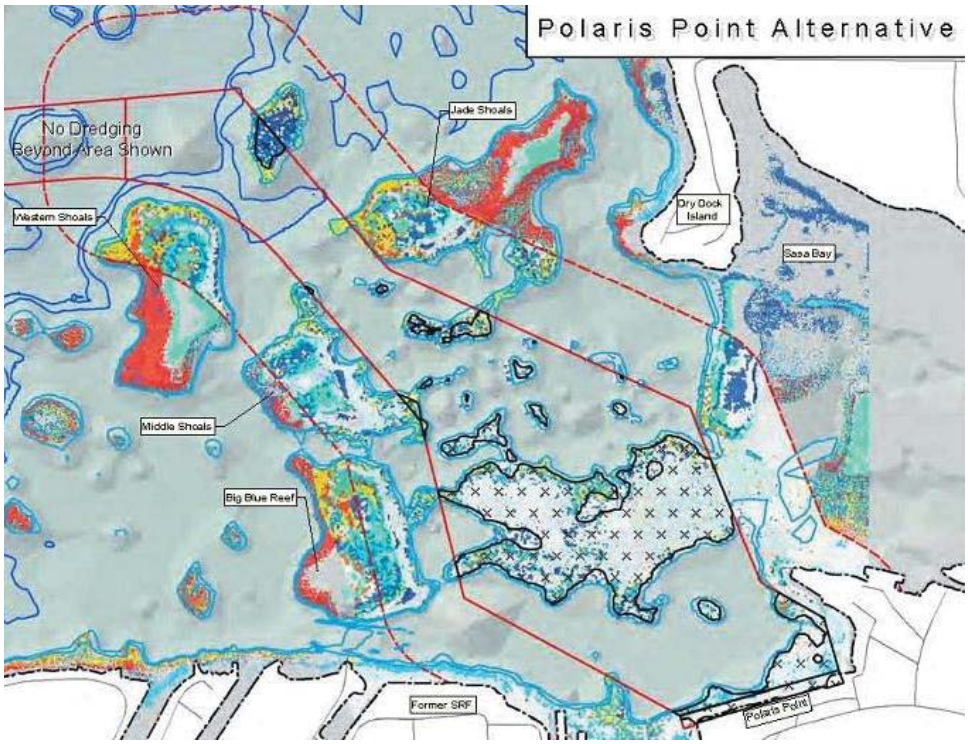

Figure 5. The area of impact expected for dredging in outer Apra Harbor. Direct impacts would be within the solid black lines. Indirect impacts due to suspended sediment would be contained within the dashed lines (USN 2010).

5.3 Response

This section analyzes the responses of green and hawksbill turtles to the 2 stressors associated with the proposed action that were identified above as likely to result in adverse effects to green and hawksbill turtles: 1) Adverse levels of sound energy during pile driving operations in Apra Harbor; and 2) impacts of lost or degraded sheltering and forage habitat due to dredging in outer Apra Harbor.

5.3.1 Response to Elevated Noise Levels during Pile Driving

The proposed action involves about 2 years of round-the-clock pile driving: 550 days to drive the sheet and H-piles, and 205 days to drive the pipe piles. The probable response to exposure to pile driving noise would be the movement of a low, but unknown number of turtles away from sheltering and forage habitats located at or near the proposed CVN wharf and turning basin. Because turtles appear to be relatively acoustically unresponsive, particularly when compared to marine mammals, NMFS expects that affected turtles may move a short distance away from the proposed pile driving if received levels exceed their tolerance thresholds, which are presently unknown. As described above in subsection 5.2.1.2, the 180 dB isopleth is expected at about 34 m from the CVN wharf, whereas the 160 dB isopleth would be at about 750 m. Although the 160 dB isopleth for inner harbor pile diving is expected to occur at 1,000 m, in the area where turtles are expected, that isopleth occurs within the expected footprint of the 160 dB isopleth for the CVN wharf (Figure 4). No specific information is available to estimate the lateral movement that would be expected for sea turtles under these circumstances. However, NMFS expects that after initially moving away, some exposed turtles may move back toward the area as they become conditioned to the new stimulus. Although it is conceivable that some turtles may remain within the area where they may experience some low level of TTS, NMFS expects that no sea turtles would be injured by exposure to pile driving sounds, and the potential TTS should have no

measurable impacts on the turtles' ability to forage, shelter, and avoid predators or other threats such as vessels. The 160 dB isopleth for CVN wharf pile driving could extend outward to a little over half the width of the channel into Sasa Bay. It is possible that some turtles may be initially discouraged from entering or exiting Sasa Bay during while pile driving is occurring. However, as mentioned above, after an initial period of possible avoidance, affected turtles are likely to become conditioned to the on-going noise and return to normal transits to and from Sasa Bay.

Based on the information above, NMFS expects that no sea turtles would be directly injured by this stressor, but an unknown number of green and hawksbill turtles are expected to experience behavioral modification in the form of temporary areal avoidance of an area equivalent to about 3.2% of Guam's available turtle habitat (including the inner harbor), before they become conditioned to the new stimulus and reclaim some of the area, where they may experience some level of TTS. Although this would be an adverse affect, the significance of this impact is not expected to rise to the level of take. Normal behaviors and areal access are expected to return soon after the cessation of pile driving (dredging impacts on habitat not withstanding).

5.3.2 Response to Loss or Degradation of Sheltering and Forage Habitat

As described at subsection 5.2.2.1, the area proposed for dredging the CVN turning basin and wharf contains turtle sheltering and forage resources, which are expected to be reduced or eliminated as a result of the proposed dredging. Consequently, in addition to the "temporary" movement away from the area due to project activities and elevated noise levels, some resident turtles would likely permanently avoid the area in favor of less impacted habitats in adjacent areas of the harbor, and reduced sheltering and forage resources would be available to transient turtles moving to and from Sasa Bay.

The estimated 53-acre foot print for the proposed dredging consists of a mix of benthic habitats "patches", several of which currently support varying amounts of sloped structure, macroalgae, and sponge growth that constitute turtle sheltering and forage resources. Because those habitat patches are disjoint and spread around the 53-acre footprint, NMFS considers the entire area turtle habitat that would be lost or degraded as a result of the proposed action. An additional 119 acres of adjacent habitat is expected to be indirectly and temporarily impacted by dredging-related sedimentation. Algae and sponges may recolonize some of the dredged area over time. However, the dredging is expected to reduce the area's rugosity (the area would be made flatter). Therefore, the amount of potential sheltering habitat is expected to be permanently reduced. Also, the area of sediment-covered substrate would likely increase, thus suitable substrate for sponge and algal growth is expected to be permanently reduced. Because underutilized sheltering and forage resources are readily available on the adjacent reef areas, NMFS expects that no sea turtles would experience any reduction in vitality due to reduced availability of these resources in the dredged area.

Based on the information above, NMFS expects that no sea turtles would be directly injured or killed by this stressor. However, an unknown number of turtles are expected to experience behavioral modification in the form of temporary or permanent areal avoidance of up to 172 acres of potential habitat at the eastern end of the outer harbor representing about 0.7% of potential island-wide turtle habitat. Those turtles are also expected to experience behavioral modification in the form of permanently lost or degraded sheltering and forage resources

formerly available within the 53-acre dredging footprint, which represents about 0.2% of potential island-wide turtle habitat. Normal behaviors and areal access are expected to return to the non-dredged areas soon after the cessation of dredging. Although this would be an adverse affect, based on the expectation that no injury or vitality reduction would be experienced, the magnitude of this impact is not expected to rise to the level of take.

5.4 Risk

This section analyzes the risk posed by the proposed action to green and hawksbill sea turtles due to the 2 stressors associated with the proposed action that were identified above as likely to result in adverse effects to green and hawksbill turtles: 1) Adverse levels of sound energy during pile driving operations in Apra Harbor; and 2) impacts of lost or degraded sheltering and forage habitat due to dredging in outer Apra Harbor.

5.4.1 Risk from Elevated Noise Levels during Pile Driving

Based on the available data used in the exposure and response analyses above, we expect that a low but undeterminable number of green and/or hawksbill turtles may be harassed, through behavioral modification in the form of temporary areal avoidance of habitat at the eastern end of the outer harbor equivalent to about 3.2% of Guam's available turtle habitat. No turtles are expected to be directly injured or killed, but some of these turtles could potentially experience low level TTS that would have no measurable impacts on the turtles' ability to forage, shelter, and avoid predators or other threats. As described above in the Status of Listed Species section, resident turtles on Guam likely belong to multiple NAs located elsewhere in Oceania, whereas turtles nesting on Guam likely forage elsewhere. However, genetic information is inadequate to determine which NAs within Oceania the affected resident turtles belong to. Additionally, although we do not know the exact number of animals that would be affected, we know that the number would be extremely small in comparison to the number of individuals of the affected species found across Oceania, and even larger numbers represented around the world. Given the low number of turtles expected to be affected, that those animals would most likely be from multiple NAs, and the expectation that no injury or reduction in fitness would result due to these stressors, the risk to the affected nesting aggregations is considered negligible.

5.4.2 Risk from Loss or Degradation of Sheltering and Forage Habitat

Based on the available data used in the exposure and response analyses above, we expect that a low but undeterminable number of green and/or hawksbill turtles may be harassed, through behavioral modification in the form of permanently lost or degraded sheltering and forage resources at the eastern end of the outer harbor within the 53-acre dredging footprint (0.2% of potential island-wide turtle habitat), and through temporary or permanent areal avoidance of 53 to 172 acres of potential habitat, representing up to about 0.7% of potential island-wide turtle habitat.

Although the expected resource losses and areal avoidance would be adverse affects on these turtles, no turtles are expected to be directly injured or killed, nor would they experience any measurable reduction in fitness. As described above in the Status of Listed Species section, resident turtles on Guam likely belong to multiple NAs located elsewhere in Oceania, whereas turtles nesting on Guam likely forage elsewhere. However, genetic information is inadequate to determine which NAs within Oceania the affected resident turtles belong to. Also, although we

do not know the exact number of animals that would be affected, we know that the number would be extremely small in comparison to the number of individuals of the affected species found across Oceania, and even larger numbers represented around the world. Given the low number of turtles expected to be affected, that the animals would most likely be from multiple NAs, and the expectation that no injury or reduction in fitness would result due to these stressors, the risk to the affected nesting aggregations is considered negligible.

5.5 Cumulative Impacts

"Cumulative Impacts" are the additive, synergistic, multiplicative, and/or antagonistic effects that may result from interactions between and among the stressors produced by an action and other pre-existing stressors. Based on prevailing currents, and because foraging turtles show strong fidelity for preferred foraging areas, NMFS is doubtful that, with the exception of collision, in-harbor impacts are likely to interact with the expected out-of-harbor impacts. As such, those areas are discussed individually. As discussed environmental baseline section, turtles within Apra Harbor are routinely exposed to stressors that include: 1) elevated in-water noise levels due to harbor activities and vessel traffic related to the naval station and the commercial port; 2) reduced water quality due to runoff from industrial areas, shipboard effluents, and sediment-laden streams; 3) reduced benthic habitat quality due to previous blasting and dredging, as well as on-going anchoring and sediment-laden river runoff; and 4) light pollution on nesting beaches due to nighttime harbor operations. Outside the harbor, turtles are exposed to stressors that include: 1) on-going intentional take; 2) runoff that transports anthropogenic pollutants and sediments; and 3) poorly treated wastewater effluents.

The proposed in-harbor work is expected to result in increased ambient noise levels in the harbor, which would also spread outward somewhat into the Philippine Sea to the west. This would be particularly so during the 2 years of proposed impact pile driving, but would also persist over current levels due to the expected increase in number and frequency of vessels visiting the harbor. Despite the high level of attention in-water noise has been receiving in recent years, the impacts of increased noise levels in the harbor are less worrisome than the subtle but inexorable shift in the harbor's health and ecology toward an industrial harbor that would eventually be incapable of supporting its current level of diversity, which is undoubtedly much lower than it was prior to the 1940s. Dredging and wharf work would result in a continued trend away from natural shorelines and benthic substrates at the east end of the harbor, and extend those impacts incrementally westward into the more pristine areas of the harbor. Although its impact has been determined to be insignificant, the proposed action would result in increased nighttime artificial light levels in the harbor, representing a small but incremental shift further away from the natural conditions upon which green and hawksbill turtles depend.

Outside of the harbor, turtles are exposed to on-going intentional take (harvest of adults and juveniles in nearshore waters, and the take of nesting adults and nests onshore), and the nearshore reefs have been impacted by point and non-point discharges that have introduced sediments and pollutants at ever increasing rates. This has altered and degraded benthic communities upon which ESA-listed sea turtles depend, while simultaneously directly exposing the turtles to potentially harmful substances. Although the impact of the expected increased effluent flow has been determined to be insignificant, without improved treatment, the proposed

increased effluent flow represents another incremental shift away from the natural processes green and hawksbill turtles depend upon.

Although the cumulative impacts of the proposed action are not expected to synergistically exceed any threshold of adverse affect for ESA-listed marine species, the proposed action is expected to result in the continued incremental shift away from natural processes within Apra Harbor, and along Guam's west shoreline, toward impacted benthic communities that are becoming increasingly incapable of aiding in the recovery of ESA-listed sea turtles. Implementation of the conservation recommendations described later in this opinion would help reduce this trend.

6 Cumulative Effects

"Cumulative effects," as defined in the ESA implementing regulations, are limited to the effects of future State, tribal, local, or private actions that are reasonably certain to occur in the action area considered in this Opinion (50 CFR 402.02). Cumulative effects, as defined in the ESA, do not include the continuation of actions described under the Environmental Baseline, and future Federal actions that are unrelated to the proposed action are not considered in this section because they require separate consultation pursuant to Section 7 of the ESA. Expansion of the Port Authority's facilities at the Guam Commercial Harbor is under consideration to support future island growth, including the proposed action. This work could include construction dredging on the north side of the Apra Harbor that would be on the same scale as the dredging proposed in this action. However, because funding for the harbor expansion is uncertain, that action is considered separate and unrelated to the proposed action considered in this opinion. Consequently, that project will not be considered here.

Other sources of cumulative effects (fisheries interactions, vessel traffic, and marine debris) are described in the Environmental Baseline section, and are not only expected to continue, but are likely intensify over time, causing cumulative effects on green and hawksbill sea turtles. The expected dramatic growth of the human population on Guam, as well as across the rest of the Pacific region, would likely result in increased coastal development, fishing pressure, vessel traffic, and pollution of the marine environment. Impacts may include accelerated degradation or loss of forage, resting, and nesting habitats; increased take in fisheries including intentional harvest of turtles and eggs; increased vessel strikes; and increased entanglement in, and ingestion of, marine debris. Although the extent of these increased stressors is unquantifiable, and the corresponding effects are also unquantifiable, it is clear that unless adequately addressed to reduce their impacts, these vectors of cumulative effect would present increasing challenges to the continued survival of green and hawksbill sea turtles.

Global climate change is expected to continue and will therefore continue to impact sea turtles and their habitats. Rising temperatures at nesting beaches may continue to exacerbate a female bias and could also increase embryonic mortality if beaches are already at the high end of thermal tolerance for sea turtle nests (Matsuzawa *et al.* 2002). Only low level nesting of greens and hawksbills takes place inside the action area. However turtles that occur in the action area come from nesting aggregations that may be affected by impacts at their nesting beaches of origin throughout the Pacific. The best available demonstrations of the potential effects of sea level rise indicate that some sea turtle nesting beaches will lose a percentage of their

current area by 2100 (Fish *et al* 2005; Baker *et al* 2006; Fuentes *et al* 2009). However, these were modeled on static systems and did not account for geomorphological dynamics. A quantitative analysis of physical changes in 27 atoll islands in the central Pacific over a 19 to 61 year period, that corresponds with a rate of sea level rise of 2.0 mm per year, shows that 86% of islands remained stable (43%) or increased in area (43%) while only 14% of study islands exhibited a net reduction in island area (Webb & Kench 2010), evidence that changes will not be uniform or predictable and sea level rise may or may not result in beach loss.

Alterations to foraging habitats and prey resources, changes in phenology and reproductive capacity that correlate with fluctuations in SST, and potential changes in migratory pathways and range expansion (all discussed previously in Environmental Baseline) are additional ways in which sea turtles may continue to be impacted by climate change. Many marine species, including the pelagic life stages of sea turtles in the action area, forage in areas of nutrient rich oceanic upwelling, the strength, location, and predictability of which may change with increasing global temperatures (Harwood 2001).

Although there is much speculation on the potential impacts of climate change on species and ecosystems, there are multiple layers of uncertainty associated with these analyses making it impossible to accurately predict the most likely scenario that will result and consequently what impacts species and ecosystems will face, particularly in Pacific Island countries (Barnett 2001). Effects of climate change will not be globally uniform (Walther *et al* 2002) and information regarding the magnitude of future climate change is speculative and fraught with uncertainties (Nicholls and Mimura 1988). In particular, there is no comprehensive assessment of the potential impacts of climate change within the action area or specific to sea turtles that may be within the action area.

In addition to the uncertainty of the rate, magnitude, and distribution of future climate change and its associated impacts on temporal and spatial scales, the adaptability of species and ecosystems are also unknown. Impacts of climate change and hence its 'seriousness' can be modified by adaptations of various kinds (Tol *et al* 1998). Ecological systems evolve in an ongoing fashion in response to stimuli of all kinds including, climatic stimuli (Smit *et al* 2000). Sea turtles may exhibit a variety of adaptations to cope with climate change impacts although it will likely take decades to centuries for these shifts to occur (Limpus 2006) making it increasingly difficult to predict future impacts of climate change on sea turtles in the action area. For example, sea turtles are known to be highly mobile and in the past have shown the ability to adapt to changes in their environment and relocate to more suitable foraging and nesting sites over the course of multiple generations. Implications of climate change at the population level are a key area of uncertainty and one of active research (e.g. Jonzén *et al* 2007) and cannot currently be reliably quantified in terms of actual mortalities resulting from climate change impacts over any time scale. Nor can they be qualitatively described or predicted in such a way that could be more meaningfully evaluated in the context of this biological opinion. Within the temporal scale of the proposed action, any future synergistic impacts of climate change in the action area that might interact with the effects of the proposed action are not considered significant.

7 Integration and Synthesis of Effects

The purpose of this Opinion is to determine if the proposed action is likely to jeopardize the continued existence of listed species (50 CFR 402.02). "Jeopardize the continued existence of" means to engage in an action that reasonably would be expected, directly or indirectly, to reduce appreciably the likelihood of both the survival and recovery of a listed species in the wild by reducing the reproduction, numbers, or distribution of that species. This opinion considers the Effects of the Action within the context of the Status of Listed Species and Environmental Baseline, as described in the Approach section (beginning of Section 7 Effects of the Action). We determine if reduction in fitness to individuals of listed species resulting from the proposed action are sufficient to reduce the viability of the populations those individuals represent (measured using changes in the populations' abundance, reproduction, spatial structure and connectivity, growth rates, or variance in these measures to make inferences about the population's extinction risks). In order to make that determination, we use the population's base condition as the context for the overall effects of the action on the affected populations. Finally, our Opinion determines if changes in population viability are likely to be sufficient to reduce the viability of the species those populations comprise or impair long term recovery of those species, consistent with recovery objectives, as set forth in the species' recovery plan and other sources. The following discussion summarizes the probable risks the proposed action poses to green and hawksbill sea turtles by integrating the Effects of the Action, Status of Listed Species, Environmental Baseline, and Cumulative Effects sections of this opinion

Parmesan and Yohe (2003) consider climate change a driver of small-magnitude but consistent impact that is important in that it systematically affects century-scale biological trajectories and ultimately the persistence of species. Based on this consideration and the uncertainties in predicting future impacts described earlier, the significance of climate change in the context of this analysis is low considering the limited temporal and spatial scale over which the action is likely to occur. There is currently no demonstrated link between climate change-induced environmental impacts such as sea level rise and marine turtle population indices in the modern record. This may be because most sea turtle data sets only overlap with the most recent 20-50 years of climate data, a period which is not long enough to discern changes in climate directly linked to anthropogenic causes.

As indicated above in the description of the proposed action, the action components that potentially affect ESA-listed species under NMFS jurisdiction consist of construction of vessel berthing and related facilities, as well as harbor dredging in Apra Harbor. Additional indirect effects are expected to result from increased wastewater discharge, as well as an increase in commercial vessel traffic in Apra Harbor. The total period of construction is approximately 10 years. Pile driving and dredging operations are expected to last about 2 to 3 years. We anticipate that over the expected timeframe of the action and within the action area, recent and future mortalities that can be linked directly to climate change impacts will not be discernible because non-climate related causes dominate local, short-term biological changes. Also, it is difficult to predict how the uncertain effects of climate change will impact sea turtles when combined with other threats. Although it is likely that some sea turtle nesting sites will lose a percentage of their area to rising sea levels and typhoon activity, the synergistic impacts of these threats in the action area, and the sea turtles' ability to adapt, remain uncertain. In summary, as discussed previously in the Status of the Species, Environmental Baseline, and Cumulative Effects sections, very little

scientific data have been collected regarding the current or future impacts of anthropogenic climate change on sea turtles, either globally or in the action area. Therefore, we cannot predict with precision how climate change will continue to impact sea turtle populations or how they will adapt to environmental changes in various habitats. Based on the best available data, we conclude that climate change-related impacts to sea turtles and sea turtle adaptations to climate change are both long-term processes that will manifest over a timescale that exceeds the term of this biological opinion. Both processes are also subject to many uncertainties and are not yet well enough understood to permit more meaningful quantitative or qualitative analysis. As such, climate change-related impacts do not appear to have had a measurable impact on these species or to be likely to reduce the likelihood of recovery of these species in the context of the proposed action.

7.1 Green Sea Turtles

As described in the Effects of the Action section, we expect that:

1. A low but undeterminable number of green turtles would experience behavioral modification resulting from temporary areal avoidance of sheltering and forage habitat at the eastern end of the outer harbor equivalent to about 3.2% of island-wide turtle habitat, due to exposure to elevated noise levels during pile driving, but no injury or reduction in fitness are expected to result due from this stressor;
2. A low but undeterminable number of green turtles would experience behavioral modification resulting from the permanent loss and/or degradation of 53 acres of sheltering and forage habitat at the eastern end of the outer harbor equivalent to about 0.2% of island-wide turtle habitat. They would also experience behavioral modification resulting from temporary or permanent areal avoidance of up to 172 acres of sheltering and forage habitat, representing up to about 0.7% of island-wide potential turtle habitat during the dredging operations, but no injury or reduction in fitness are expected to result due from these stressors; and
3. In addition to the effects resulting from the 2 stressors above, and as described in the cumulative impacts sub-section of the Effects section, the proposed action is expected to result in an incremental but permanent reduction in green turtle habitat quality, which is a continued movement away from the natural processes upon which Guam's green turtles depend.

As discussed in Status of Listed Species, about 18,000 to 38,000 green turtles nest annually in Oceania (adult females only), and about 150 to 250 green turtles reside in the nearshore waters of Guam (juveniles and adults of both sexes). As summarized in Figure 2, many of the major green sea turtle nesting aggregations in Oceania are stable or increasing, while many of the smaller nesting aggregations are declining. As discussed in the Environmental Baseline, most green turtle nesting and foraging areas on Guam have been impacted by coastal development and pollution, while intentional harvest of turtles continues in some areas, and fisheries interactions and boat collisions likely take low numbers of turtles.

As discussed more fully in the Cumulative Effects and Environmental Baseline sections, the effects of climate change, fisheries interactions, vessel traffic, and marine debris within the action area are expected to continue, and likely worsen, in the future. Although the impact and time scale of these effects on the trajectory of the affected green turtle populations is currently

uncertain, those impacts are expected to occur on a time scale, against which the impacts of the proposed action would be indistinguishable.

As described in the effects analysis, although the proposed action is anticipated to result in no take of green turtles, it could result in the loss, degradation, or avoidance of less than 1% of the available sheltering and forage habitat around Guam. Based on the available information, sheltering and forage habitat is not a limiting factor for green turtles around Guam. As described in the Environmental Baseline section, the habitat to be lost or degraded has been heavily impacted by previous and on-going activities, and it is located in the middle of a heavily used channel. Additionally, under-utilized habitat of equal or greater value is readily available in adjacent areas. Consequently, the habitat impacts expected to result from the proposed action is not expected to reduce the reproduction or abundance of green sea turtles at Guam or to impede the recovery of that species around the island.

As described above in the status of the species section, the turtles found in Guam's waters represent a very small proportion of green turtles across Oceania. They originate from multiple NAs (likely at least 3; Japan, the Philippines, and Guam), and the largest NAs in Oceania are increasing. Although trend information is unavailable for Guam and the Philippines, abundance appears to be increasing for the Japan NA. Given that the proposed action is expected to result in no take of green turtles, we do not expect the impacts of the proposed action to reduce the reproduction, abundance, or distribution, or recovery of the affected green sea turtle NAs. As such, the proposed action is not expected to adversely affect the recovery of green sea turtles in Oceania. Therefore, when taken in context with the status of the species, the environmental baseline, cumulative impacts and effects, the proposed action is not likely to appreciably reduce the likelihood of survival and recovery of this species, as listed under the ESA.

7.2 Hawksbill Sea Turtles

As described in the Effects of the Action section, we expect that:

1. A low but undeterminable number of hawksbill turtles would experience behavioral modification resulting from temporary areal avoidance of sheltering and forage habitat at the eastern end of the outer harbor equivalent to about 3.2% of island-wide turtle habitat, due to exposure to elevated noise levels during pile driving, but no injury or reduction in fitness are expected to result due from this stressor;
2. A low but undeterminable number of hawksbill turtles would experience behavioral modification resulting from the permanent loss and/or degradation of 53 acres of sheltering and forage habitat at the eastern end of the outer harbor equivalent to about 0.2% of island-wide turtle habitat. They would also experience behavioral modification resulting from temporary or permanent areal avoidance of up to 172 acres of sheltering and forage habitat, representing up to about 0.7% of island-wide potential turtle habitat during the dredging operations, but no injury or reduction in fitness are expected to result due from these stressors; and
3. In addition to the effects resulting from the 2 stressors above, and as described in the cumulative impacts sub-section of the Effects section, the proposed action is expected to result in an incremental but permanent reduction in green turtle habitat quality, which is a continued movement away from the natural processes upon which Guam's hawksbill turtles depend.

As discussed in Status of Listed Species, about 5,400 to 6,100 hawksbill turtles nest annually in Oceania (adult females only). About 22 to 37 hawksbill turtles reside in the nearshore waters of Guam (juveniles and adults of both sexes). As discussed in Status of Listed Species, hawksbill sea turtle nesting aggregations in Oceania are generally decreasing. As discussed in the Environmental Baseline, most hawksbill turtle nesting and foraging areas on Guam have been impacted by coastal development and pollution. Intentional harvest of turtles continues in some areas, and fisheries interactions and boat collisions likely take low numbers of turtles.

As discussed in the Cumulative Effects section, the effects of climate change, fisheries interactions, vessel traffic, and marine debris within the action area are expected to continue, and likely worsen, in the future. Although the impact and time scale of these effects on the trajectory of the affected hawksbill turtle populations is currently uncertain, those impacts are expected to occur on a time scale, against which the impacts of the proposed action would be indistinguishable.

As described in the effects analysis, although the proposed action is anticipated to result in no take of hawksbill turtles, it could result in the loss, degradation, or avoidance of less than 1% of the available sheltering and forage habitat around Guam. Based on the available information, sheltering and forage habitat is not a limiting factor for hawksbill turtles around Guam. As described in the Environmental Baseline section, the habitat to be lost or degraded due to the proposed action has been heavily impacted by previous and on-going activities, and it is located in the middle of a heavily used channel. Additionally, under-utilized habitat of equal or greater value is readily available in adjacent areas. Consequently, the habitat impacts expected to result from the proposed action is not expected to reduce the reproduction or abundance of hawksbill sea turtles at Guam or to impede the recovery of that species around the island.

As described above in the status of the species section, the hawksbills found in Guam's waters represent a very small proportion of green turtles across Oceania. They likely originate from multiple NAs. The number and locations of which are currently unknown, but the population trends at those NAs could be decreasing. Given that the proposed action is expected to result in no take of hawksbill sea turtles at Guam we do not expect the impacts of the proposed action to reduce the reproduction, abundance, or distribution of the affected hawksbill sea turtle NAs, and as such, would not aversely affect the recovery of those NAs. As such, the proposed action is not expected to adversely affect the recovery of hawksbill sea turtles in Oceania. Therefore, when taken in context with the status of the species, the environmental baseline, cumulative impacts and effects, the proposed action is not likely to appreciably reduce the likelihood of survival and recovery of this species, as listed under the ESA.

8 Conclusion

After reviewing the current status of ESA-listed green and hawksbill sea turtles, the environmental baseline for the action area, the effects of the proposed action, and the cumulative effects, it is NMFS' Opinion that the U.S. Navy's proposed Guam and Commonwealth of the Northern Mariana Islands Military Relocation is not likely to jeopardize the continued existence of green sea turtles or hawksbill sea turtles.

As described above in Section 3, no critical habitat has been designated or proposed for designation for any ESA-listed marine species in the action area or elsewhere in the Mariana Archipelago. Therefore, the proposed action would have no effect on designated or proposed critical habitat under NMFS jurisdiction.

9 Incidental Take Statement

Section 9 of the ESA and protective regulations pursuant to Section 4(d) of the ESA prohibit the take of endangered and threatened species without a special exemption. "Take" is defined as to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, collect, or attempt to engage in any such conduct. "Incidental take" is defined as take that is incidental to, and not the purpose of, the carrying out of an otherwise lawful activity. Under the terms of Section 7(b)(4) and section 7(o)(2), taking that is incidental to and not intended as part of the agency action is not considered to be prohibited taking under the ESA provided that such taking is in compliance with the reasonable and prudent measures and terms and conditions of the Incidental Take Statement (ITS).

Based on the best information available, implementation of the proposed action is expected to adversely affect an undeterminable number of green and hawksbill sea turtles, primarily through behavioral modification as described in the Integration and Synthesis of Effects section. Although NMFS has determined that the proposed action is likely to adversely affect green and hawksbill sea turtles, we have also determined that the expected impacts would not rise to the level of take of those animals. Because no take is expected, no ITS is necessary, nor can an ITS be issued for this action.

10 Conservation Recommendations

Section 7(a)(1) of the ESA directs Federal agencies to utilize their authorities to further the purposes of the ESA by carrying out conservation programs for the benefit of endangered and threatened species. Conservation recommendations are discretionary agency activities to minimize or avoid adverse effects of a proposed action on listed species or critical habitat, to help implement recovery plans, or develop information.

The following conservation recommendations are provided pursuant to Section 7(a)(1) of the ESA:

1. The Navy is strongly encouraged to employ acoustic attenuation devices, such as bubble curtains, to reduce the acoustic impacts of pile driving.
2. The Navy is strongly encouraged to monitor and report the amount of dredging that occurs. The Navy shall develop a protocol that utilizes Geographic Information System (GIS) to monitor location of the dredge, and document dredging to ensure that dredging does not exceed the intended footprint and/or total acreage. The protocol should include a trigger to ensure that project management is notified when dredging approaches 53 acres dredged, or when dredging starts to go outside the intended footprint, with a clear mechanism in place to ensure that those limits are not exceeded.
3. The Navy is strongly encouraged to minimize artificial illumination visible at Spanish Steps.

a. The Navy should assess and document light levels at the Spanish Steps nesting beach, to include: preconstruction; construction, including during CVN dredging; and post construction to ensure that lights visible from the nesting beach and nearby waters are minimized to the greatest extent possible.
b. NMFS recognizes the Navy's need to provide adequate illumination to ensure safe operations 24 hours a day. However, lighting selected for the harbor should be minimized through reduction, shielding, lowering and appropriate placement of lights to avoid excessive illumination of nearshore areas and waters while meeting all safety and security regulations. Where applicable, long wavelength light sources, such as low pressure sodium or amber or red LED, are recommended.
c. To meet light reduction goals, unnecessary lighting should be turned off; as such NMFS also recommends installation of lighting systems that employ variable power settings that provide low-intensity "turtle-friendly" settings as well as full operational light settings, with the understanding that lower illumination levels would be employed during periods when the area is not in full operational use and/or not specifically required.
d. The Navy should, within safety constraints, require construction crews to reduce their lighting so that westward visibility of those lights is minimized, particularly during nighttime dredging. As above, construction lighting should be minimized through reduction, shielding, lowering and appropriate placement of lights to avoid excessive illumination of the water surface and to prevent or minimize visibility of lights from the nesting beach. Shielded low pressure sodium vapor lights are recommended for lights on offshore equipment that cannot be eliminated and for illumination of waters. Construction light intensity must be reduced to the minimum standard required by OSHA for General Construction areas, in order not to misdirect sea turtles. Shields should be affixed to the light housing and be large enough to block all light from being transmitted outside the construction area.
e. Work with the Guam Port Authority to encourage their adoption of similar lighting practices at the commercial port facilities in Apra Harbor.

4. The Navy is strongly encouraged to reduce the effects of wastewater effluent on the marine environment.
    a. The Navy should secure the required funding and commit to upgrading the HWTP and the NDWTP to secondary treatment standards or better.
    b. The Navy should monitor the impacts of wastewater effluent, particularly at the NDWTP outfall, including: performing benthic habitat surveys at the NDWTP outfall to assess pre-build-up habitat conditions, as well as turtle distribution and habitat use in the area; and performing water quality surveys to document down-plume productivity impacts as well as assessing bioaccumulation in the down-plume trophic web.
5. The Navy is strongly encouraged to initiate efforts to reduce the impacts of vessels on sea turtles around Guam. The Navy should require protected species related training for all DoD military and civilian personnel stationed in the Marianas, as well as their dependants. This training should include information about the special status of sea turtles as well as providing standoff distances and recommended speeds to avoid

collisions, and reporting procedures for interactions and strandings. This training should be developed with the assistance of NMFS Protected Resources Division.

6. The Navy is strongly encouraged to perform quarterly trash and debris removal from the Spanish Steps nesting beaches, as well as periodic efforts to replace non-native vegetation with appropriate native species, to improve turtle nesting success.
7. The Navy should pursue its intention to enter into a Memorandum of Understanding (MOU) with relevant Federal resource agencies, to include NMFS, to develop a better understanding of turtle population dynamics in the Marianas.
8. The Navy is strongly encouraged to undertake hatchling orientation studies at Spanish Steps to assess the extent to which hatchlings are attracted to harbor lighting rather than migrating directly out to sea.
9. The Navy is strongly encouraged to apply for and acquire relevant federal permits to undertake turtle programmatic activities on their properties to facilitate effective and collaborative monitoring and management activities (to include standardized nesting beach monitoring activities and nest inventories to assess reproductive success).
10. The Navy is strongly encouraged to support efforts to reduce the effects of wastewater effluent, such as bringing the Hagatna and Northern District Wastewater Treatment Plants up to secondary treatment standards or better.

11 Reinitiation Notice

This concludes formal consultation on The U.S. Navy's proposed Guam and Commonwealth of the Northern Mariana Islands (CNMI) Military Relocation. As provided in 50 CFR 402.16, reinitiation of formal consultation is required where discretionary Federal agency involvement or control over the action has been retained or is authorized by law, and if:

1. A take occurs;
2. New information reveals effects of the agency action that may affect listed species or critical habitat in a manner or to an extent not considered in this Opinion;
3. The agency action is subsequently modified in a manner that may affect listed species or critical habitat to an extent, or in a manner not considered in this Opinion; or
4. A new species is listed or critical habitat designated that may be affected by the action.

Introduction

Section 7(a)(2) of the Endangered Species Act of 1973, as amended (ESA; 16 U.S.C. 1539(a)(2)) requires each Federal agency to insure that any action they authorize, fund, or carry out is not likely to jeopardize the continued existence of any endangered or threatened species or result in the destruction or adverse modification of critical habitat of such species. To "jeopardize the continued existence" means "to engage in an action that reasonably would be expected, directly or indirectly, to reduce appreciably the likelihood of both the survival and recovery of a listed species in the wild by reducing the reproduction, numbers, or distribution of that species" (50 CFR 402.02). A Federal agency is required to consult formally with the National Marine Fisheries Service (NMFS) for marine species or their designated critical habitat or with the United States Fish and Wildlife Service (USFWS) for terrestrial and freshwater species or their designated critical habitat when that agency's action "may affect" an ESA-listed species. Federal agencies are exempt from the requirement for formal consultation if they have received from NMFS or USFWS written concurrence with a determination that an action "may affect, but is not likely to adversely affect" ESA-listed species or their designated critical habitat (see ESA Section 7 Implementing Regulations; 50 CFR 402).

This document represents NMFS' biological opinion (Opinion) of the effects on marine species protected under the ESA that may result from the repair and modernization of about 2,500 linear feet of existing waterfront structures at Sumay Cove, in Apra Harbor, Guam. This Opinion is based on the review of: the U.S. Navy's (Navy) June 1, 2011, Biological Assessment (BA) for Sumay Cove Repair and Modernization, Naval Base Guam; recovery plans for U.S. Pacific populations of listed sea turtles; published and unpublished scientific information on the biology and ecology of threatened and endangered marine species, as well as of other species of concern in the action area; monitoring reports and research in the region; biological opinions on similar actions; and relevant scientific and gray literature (see Literature Cited).

1 Consultation History

Informal consultation between the Naval Facilities Engineering Command Marianas (NAVFACMAR hereafter referred to as the Navy) and NMFS Pacific Islands Regional Office (PIRO) was completed on February 10, 2009, for the proposed installation of a floating dock system at the Sumay Cove Marina (NMFS PCTS File No. I/PIR/2008/07331, PIRO Reference No. I-PI-08-717-LVA). In early October 2010, the Navy contacted PIRO Protected Resources Division (PRD) to discuss the changes to the proposed action covered under the 2009 informal consultation. On October 13, 2010, PIRO PRD recommended, via electronic mail (e-mail), that formal consultation would be appropriate for the modified action. Subsequent to that, numerous communications were shared via phone and e-mail, and a site visit was conducted with personnel from the Navy and PIRO Habitat Conservation Division (HCD) in attendance. On June 21, 2011, NMFS PIRO received the Navy's June 10, 2011, request for formal consultation, which stated the Navy's determination that the proposed action would be likely to adversely affect green sea turtles (*Chelonia mydas*) and hawksbill sea turtles (*Eretmochelys imbricata*), but would be not likely to adversely affect the remaining ESA-listed marine species. The consultation request also included the Navy's June 1, 2011, BA for the action. A formal consultation was initiated on that date for green and hawksbill turtles, resulting in this Opinion.

2 Description of the Proposed Action and Action Area

The proposed action is described in the June 1, 2011, BA, and consists of Naval Base Guam performing work to repair and modernize waterfront facilities at Sumay Cove in Apra Harbor, Guam. In summary, the project consists of the operation of a land-based and barge mounted heavy equipment to complete three components: 1) Shoreline Repairs; 2) Small Craft Berthing Improvements; and 3) Boat Ramp Repairs.

Shoreline Repairs: A land-based pile driver would impact drive about 1,000 linear feet of 24-inch (61 cm) steel sheet piles along the eastern shoreline, and around two mole piers at the north end of the Sumay Cove peninsula. The new sheet piles would start near the midpoint along the existing sheet-pile seawall (Station 36+65), and continue northeasterly out and around the eastern mole pier. The western mole pier would also be re-faced with new sheet piles, but no piles would be installed along the shoreline between the two mole piers. The new piles would be driven down to about 25 feet below the mudline, about 18 inches seaward of the existing seawall. The new seawall would be tied back, the void between the previous and new seawalls would be backfilled, and new concrete pile caps and skirts would also be constructed to finish the sea wall. Pile driving would be done during normal working hours, and is expected to require 120 8-hour days to complete. No nights or Sunday work is proposed. Working 6 days a week, about 5 months of daylight pile driving is expected for this component.

Small Craft Berthing Improvements: Land-based and barge mounted heavy equipment would be used to install 55 15.5-inch octagonal concrete piles, and to install floating dock sections along about 1,670 linear feet of existing seawall, beginning at Station 36+65, and extending southwesterly (into) along the eastern side of the Sumay Cove peninsula. Heavy equipment with an auger would drill the sea floor to the desired depth then reverse drill (leaving the sediments in-place) to loosen bottom sediments before the concrete piles are impact driven to 20 feet below the mudline. Once the piles are installed, a crane would place modular concrete cells onto the water, where they would be joined to each other and connected to the pilings to form multi-berth floating docks. Gangways and service connections (water, power, and lights) would be also be installed. The total time to complete this work would be about 5 months, including about 60 days (10 weeks) of pile driving.

Boat Ramp Repairs: The two existing Moral Welfare and Recreation (MWR) Boat Ramps would be removed and replaced with expanded dimensions. One ramp would be widened by about 6 feet; the other would be lengthened by about by about 6 feet. The existing ramps would be chipped away to expose the existing rebar, expanded reinforcement would be installed, forms would be placed, and concrete would be pumped into the forms. This component is expected to take about 25 days to complete.

In addition to the work described above, divers may be used if necessary to repair equipment or to perform inspections.

Appropriate conditions and best management practices (BMP) are detailed in the BA and would apply to this action. These protective measures would include requirements to maintain constant vigilance for the presence of ESA-listed marine species during all aspects of the proposed action, to postpone or halt work (particularly pile driving) when protected species are within 50 yards

(46 m) of the work, to properly install and maintain silt curtains and erosion controls, to employ ramp-up techniques for pile driving, to minimize the introduction of pollutants into the marine environment, and to conduct acoustic monitoring of pile driving operations to validate or correct acoustic estimates, and to adjust safety ranges accordingly.

2.1 Interrelated/Interdependent Actions

The proposed action would result in the repair or replacement of existing waterfront structures that are currently in-use. Although the Shoreline and Boat Ramp Repairs projects would include small expansions of their original footprints, they would result in the construction of nearly identical replacement structures, located in virtually the original locations. The future use of these structures is expected to return to levels that would be effectively the same as they would have been had the proposed work not been done. Although the Small Craft Berthing Improvements component is expected to increase available vessel berthing, the proposed action is expected to result only in an increase in the number of moored vessels, not an increase in vessel traffic. Any future increase in vessel traffic at Sumay Cove would be result from population increases on the island of Guam that is unrelated to the action under consideration here. Should the mooring facilities be left unexpanded, NMFS expects that additional vessel traffic would utilize the preexisting boat ramp vice mooring at the docks. Based on this, NMFS expects no interrelated or interdependent actions to result from the proposed action.

2.2 Action Area

With regard to ESA-listed marine species under NMFS jurisdiction, the action area for this project is limited to the marine waters around Guam (Figures 1 and 4). For all work, other than pile driving, the action area is estimated to be the in-water areas of Apra Harbor within a 46-meter arc around those activities, and the down-current extent of any plumes that may result from mobilized sediments or discharges of wastes or toxic chemicals such as fuels and/or lubricants associated with the machinery used for this activity. However, during the proposed pile driving, the action area is extended seaward up to 25 km from Sumay Cove to include the waters that may be ensonified by pile-driving noise capable of eliciting behavioral response in ESA-listed marine species.

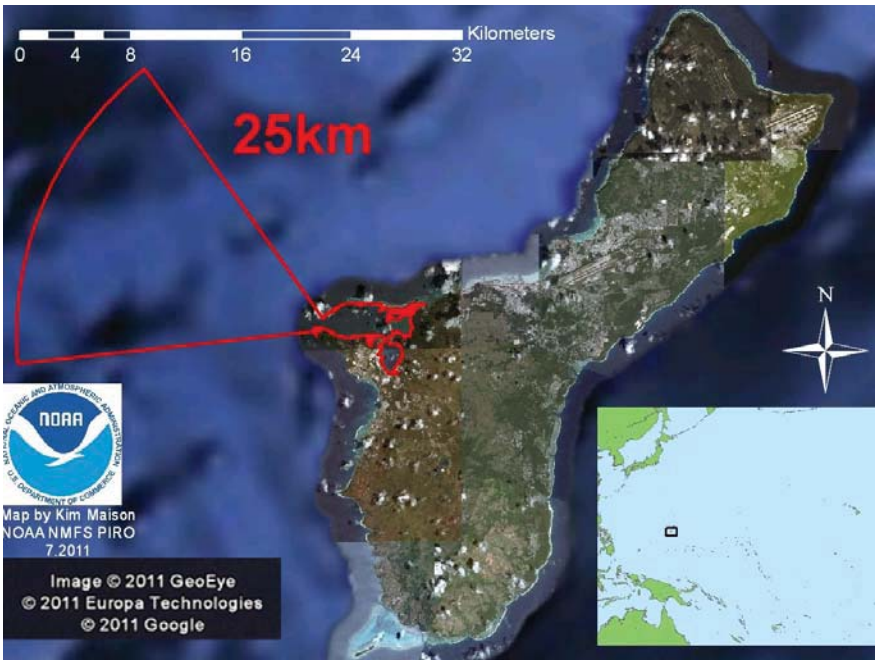

Figure 1. Action Area: Guam, with Apra Harbor and the 25-kilometer offshore area expected to be ensonified outlined in red.

3 Status of the Species

The Navy determined that the proposed action is likely to adversely affect green and hawksbill turtles, but is not likely to adversely affect blue, fin, humpback, sei, and sperm whales, as well as leatherback, loggerhead and olive ridley sea turtles (Table 1). Green and hawksbill turtles are the subject of this Opinion.

This section presents biological or ecological information for green and hawksbill sea turtles affected by the proposed action relevant to formulating the Opinion. Subsections 3.1 and 3.2 provide species-specific descriptions of distribution and abundance, life history characteristics (especially those affecting vulnerability to the proposed action), threats to the species, major conservation efforts, and other relevant information. Factors affecting those species within the action area are described in more detail in the Environmental Baseline (Section 4). No critical habitat has been designated for either of these species in the Pacific Ocean. Therefore, this project would have no effect on designated critical habitat under NMFS jurisdiction.

3.1 Green Sea Turtles

Green turtles are distributed circumglobally, and can be found in the Pacific, Indian, and Atlantic Oceans as well as the Mediterranean Sea, as described in the most recent green turtle 5-year status review (NMFS & USFWS 2007a). As shown above in Table 1, in 1978, all green turtles were listed as threatened under the ESA, except for the breeding populations in Florida and on the Pacific coast of Mexico, which were listed as endangered.

Table 1. ESA-listed marine species that may be affected by proposed action.

Species	Scientific Name	ESA Status	Listed	Federal Register
Species not likely to be adversely affected by the proposed action.				
Blue Whale	*Balaenoptera musculus*	Endangered	12/02/1970	35 FR 18319
Fin Whale	*Balaenoptera physalus*	Endangered	12/02/1970	35 FR 18319
Humpback Whale	*Megaptera novaeangliae*	Endangered	12/02/1970	35 FR 18319
Sei Whale	*Balaenoptera borealis*	Endangered	12/02/1970	35 FR 18319
Sperm Whale	*Physeter macrocephalus*	Endangered	12/02/1970	35 FR 18319
Leatherback Sea Turtle	*Dermochelys coriacea*	Endangered	06/02/1970	35 FR 8491
Loggerhead Sea Turtle	*Caretta caretta*	Threatened	07/28/1978	43 FR 32800
Olive Ridley Sea Turtle	*Lepidochelys olivacea*			
Nesting aggregations on west coast of Mexico		Endangered	07/28/1978	43 FR 32800
All other Olive Ridley Sea Turtles		Threatened	07/28/1978	43 FR 32800
Species likely to be adversely affected by the proposed action.				
Green Sea Turtle	*Chelonia mydas*			
Nesting aggregations in Florida and Mexico		Endangered	07/28/1978	43 FR 32800
All other Green Sea Turtles		Threatened	07/28/1978	43 FR 32800
Hawksbill Sea Turtle	*Eretmochelys imbricata*	Endangered	07/28/1978	43 FR 32800

3.1.1 Distribution and Abundance

Globally, most green sea turtle nesting populations declined substantially during the 20th century. Conservation efforts over the past 25 years or more appear to have had some positive results, as indicated below. However, threats and impacts persist for many green sea turtle populations (NMFS & USFWS 2007a). Following are brief descriptions of distribution and abundance of green turtles in the three major ocean basins, with more detail provided for Oceania in the Pacific Basin where the action area is located. These descriptions are based on the numbers of nesting

females, or their nests, because those are the best available methods for confirming sea turtle distribution or for estimating density and population trends.

Indian Ocean

There are numerous nesting sites for green sea turtles in the Indian Ocean. One of the largest nesting sites for green sea turtles worldwide occurs on the beaches of Oman where an estimated 20,000 green sea turtles nest annually. Based on a review of 32 index sites, declines in green turtle nesting were evident for many of the Indian Ocean index sites (Seminoff 2004). While several of these had not demonstrated further declines in the more recent past, Comoros Island and the Seychelles are the only index sites in the western Indian Ocean that showed evidence of increased nesting (NMFS & USFWS 2007a).

Atlantic Ocean / Mediterranean Sea

The 5-year status review for the species identified nine geographic areas considered to be primary sites for green sea turtle nesting in the Atlantic/Caribbean, and four in the Mediterranean and reviewed the trend in nest count data for each (NMFS and USFWS 2007a). Atlantic areas include: (1) Florida, USA; (2) Yucatán Peninsula, Mexico; (3) Tortuguero, Costa Rica; (4) Aves Island, Venezuela; (5) Galibi Reserve, Suriname; (6) Isla Trindade, Brazil; (7) Ascension Island, United Kingdom; (8) Bioko Island, Equatorial Guinea; and (9) Bijagos Archipelago (Guinea-Bissau). Mediterranean sites include: (1) Turkey; (2) Cyprus; (3) Israel/Palestine; and (4) Syria. Nesting at all of the Atlantic sites was considered to be stable or increasing with the exception of Bioko Island and the Bijagos Archipelago where the lack of sufficient data precluded a meaningful trend assessment for either site. Lack of sufficient data also precluded meaningful trend assessments for the Mediterranean sites. The most important nesting concentration for green turtles in the Atlantic is at Tortuguero, Costa Rica, where nesting has increased since the 1970s. Nest count data from 1999-2003 suggest nesting by 17,402- 37,290 females per year. These sites are not inclusive of all green sea turtle nesting in the Atlantic or Mediterranean. However, other sites support lower levels of nesting and contribute a much smaller proportion to the total number of green turtles in these areas (NMFS and USFWS 2007a).

Pacific Ocean

Green turtles occur in the eastern, central, and western Pacific. Foraging areas are found throughout the Pacific, including along the southwestern U.S. coast (NMFS and USFWS 1998a). Nesting is known to occur at hundreds of sites throughout the Pacific, with major nesting occurring in Indonesia, Malaysia, the Philippines, Australia, Micronesia, Hawaii, New Caledonia, Mexico, the Galapagos Islands, and other sites (NMFS & USFWS 2007a). Oceania is a subset of the Pacific, and includes Micronesia (where the action area is located), Melanesia, and Polynesia. In this opinion, Oceania is defined as also including Australia's Great Barrier Reef (GBR), because a high proportion of green turtles occurring in Oceania nest on the GBR. Based on the best information currently available, about 18,000 to 38,000 green turtles nest annually in Oceania (Figure 2) (NMFS 2010a).

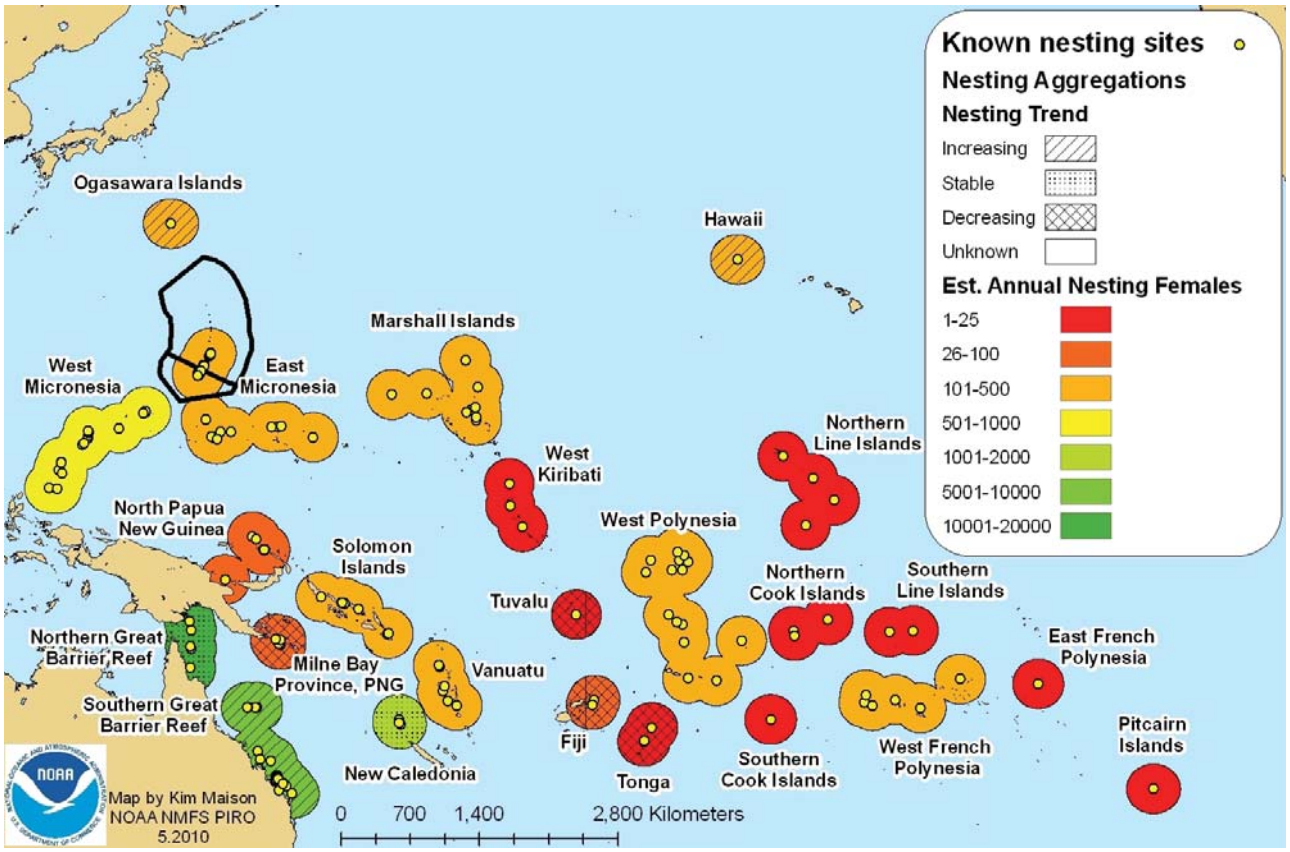

Figure 2. Green turtle nesting aggregations in Oceania.

However, about 90% of nesting takes place among two Australian nesting aggregations (NAs) (Northern GBR and Southern GBR which includes the Coral Sea Platform), with over half of all the nesting occurring on a single island; Raine Island in the Northern GBR (Chaloupka *et al*. 2008a, Limpus 2009). Nesting trends appear stable at Raine Island, and are increasing at Heron Island in the Southern GBR, as well as at Chichi-jima in the Ogasawara Islands (Chaloupka *et al*. 2008a). However, these trends do not necessarily correlate with a stable or increasing total number of turtles because of low nesting success and hatchling production at Raine Island, where the majority of nesting for Oceania occurs (Limpus *et al*. 2003; Limpus 2009). Also, NAs with small numbers of nesting females, like those throughout the islands and atolls of central and south Pacific, may be of greater importance than their proportional numbers indicate. Many of these NAs are geographically isolated, and likely harbor unique genetic diversity, which may be lost if these small NAs or their components become extirpated (Avise & Bowen 1994).

Mariana Archipelago

Sub-adult and adult green turtles occur in low abundance in nearshore waters around the Mariana Islands. Although it is likely that they occur around all of the Mariana Islands, nesting is thought to occur only in the southern islands of the CNMI and on Guam. There are no reports of turtles nesting at northern island locations. Genetic samples from nesting rookeries in the western Pacific Islands suggest that nesting greens in Guam and the CNMI are indistinguishable from each other, but distinct from those in Palau, Yap and the Marshall Islands (Dutton 2009).

Kolinski *et al*. (2004) estimated 1,000 to 2,000 turtles inhabit reef areas in the southern CNMI (Rota, Tinian, Aguiguan, Saipan, and Farallon de Mendillia). Information on nesting trend is currently insufficient for the CNMI. However, anecdotal information from residents suggests that nesting activity has decreased over time, likely as a direct result of illegal harvest (NMFS and USFWS 2007a). Since 1999, the CNMI Division of Fish and Wildlife (DFW) has monitored nesting at a minimum of five beaches on Saipan (CNMI DFW 2009), where between 4 and 18 nests are laid annually (CNMI DFW unpublished annual reports). Monitoring on Saipan, between March 4 and August 31, 2009, confirmed 16 green turtle nests, but also confirmed that three nesting turtles and three nests were poached during the same time (CNMI DFW 2009). On Tinian, nesting likely occurs on all or most of the accessible beaches (Pultz *et al*. 1999), and a July 22-31, 2009 rapid assessment yielded 35 nests at 5 beaches (CNMI DFW 2009). Eleven beaches on Rota are known to support nesting (Ilo *et al*. 2005), and a rapid assessment on July 12, 2009 yielded 13 nests (CNMI DFW 2009).

On Guam, the 5-year status review for green sea turtles reports that nesting was stable between 1990 and 2001 with the number of annual nesters fluctuating between 2 and 60 females, with nearly constant near shore abundance 150 to 250 turtles (NMFS and USFWS 2007a). Foraging and resting green turtles are often seen in close proximity to seagrass beds and reef flats, including Cocos Lagoon, Apra Harbor, Tarague Beach and several other locations around the island (Wiles *et al.* 1995). Guam's Division of Aquatic Wildlife Resources (DAWR) has maintained a bimonthly aerial survey program to monitor near shore fisheries and record opportunistic animal sightings, including marine turtles. These surveys confirm the year-round presence of a resident population of green sea turtles in Guam's nearshore waters. A total of 351 sea turtles were observed during aerial surveys between 1998 and 2008, with an annual mean of 32 turtles. Sightings include low numbers of turtles observed throughout Apra Harbor (DAWR unpublished data), and green turtles have been reported in Sumay channel by recreational boaters (Navy 2011).

Opportunistic nesting surveys counted 55 green turtle nests at various beaches around Guam between October 1, 2006 and July 31, 2008 (DAWR 2009). Known nesting beaches on Guam include: Ritidian National Wildlife Refuge, Haputo, Urunao, Tumon Bay, Cabras Island, Spanish Steps (Dangkolo and Dikiki), Cocos Island, Acho Bay, Nomña Bay, Jinapsan, and Tarague Beach (DAWR 2004; Grimm and Farley 2008). Of these beaches, two locations are on Navy lands: Haputo, and Spanish Steps, with an additional 6 to 8 unmonitored beaches occurring on Navy lands (Grimm and Farley 2008). Nesting activity peaks from April to July on Guam but often appears to continue throughout the entire year (Grimm and Farley 2008).

3.1.2 Life History Characteristics Affecting Vulnerability to Proposed Action

Following hatching at their natal beaches, green turtle hatchlings spend several years of early development in the oceanic (pelagic) zone followed by recruitment to coastal areas where post-recruitment juveniles and adults forage and mature in shallow coastal areas, feeding primarily on algae and seagrass. When on their foraging grounds, post-recruitment green turtles are often referred to as "residents". The majority of sea turtles in coastal areas spend their time at depths <5 m below the surface (Schofield *et al.* 2010, Hazel *et al.* 2009), and most resident green turtles show strong long-term site fidelity (over years) to preferred nearshore foraging and sheltering habitats, often until the habitat can no longer support their increasing size (Balazs and Chaloupka

2004; Balazs *et al*. 1987 and 1998; Chaloupka and Limpus 2001; Godley *et al*. 2003; Grant *et al*. 1997; Seminoff *et al*. 2003). Upon reaching sexual maturity, adult greens typically undertake long migrations between their resident foraging grounds and their natal nesting areas, where they mate and females nest. Nesting females are referred to as "nesters", which distinguishes them from "resident" turtles that regularly forage in that area. Although males also make mating migrations, because they do not crawl out on the beach as the females do, those males are nearly impossible to distinguish from the resident males.

Green turtle forage grounds and natal nesting areas are frequently located in different island groups, and residents at a given island group may originate from multiple natal nesting areas. Between 1971 and 1996, 46 adult female greens were flipper tagged after they nested at Rose Atoll, American Samoa. Three were recaptured; two in Fiji, and one in Vanuatu (Balazs *et al*. 1994). Between 1993 and 1995 seven post-nesting green turtles were satellite tagged at Rose Atoll. Most migrated 1,600 km to foraging areas in Fiji, and one migrated to French Polynesia (Craig *et al*. 2004). Of 513 greens tagged in French Polynesia between 1972 and 1991, six were recovered in Fiji, three in Vanuatu, two in New Caledonia, and one each were recovered in Tonga, and in the Cook Islands. Five post-nesting green turtles were satellite tracked in the Republic of the Marshall Islands (RMI) in 2007-2008. One turtle migrated to Bikini Atoll, RMI, another to Tarawa Atoll in Kiribati, one traveled to the Philippines passing through the Northern Mariana Islands, while two turtles circled for long periods of time in the open ocean with one having a final transmitted location in the exclusive economic zone (EEZ) of the Federated States of Micronesia (FSM) and the other in RMI (PIRO and PIFSC unpublished data). The last two turtles may have been exhibiting oceanic foraging strategies (Kabua *et al.* 2009). Seven post-nesting green turtles were satellite tracked from Yap, FSM during 2005-2006. Five migrated to the Philippines, one to Malaysia, and one turtle's transmitter ceased sending signals while still in the FSM (Kolinski *et al.* Draft manuscript 2007). An additional seven post-nesting greens were tracked from Yap in 2007. Four migrated to the Ryukyu Islands of Japan and three went to the Philippines (PIRO and PIFSC unpublished data). While information for Tutuila is limited, there is every reason to believe that green turtles there would display similar life history characteristics as other green turtle populations; migrating great distances between resident forage habitats and their natal beaches were they mate and nest.

Sea turtle hearing research is limited, but available information about sea turtle sensory biology suggests that they are low frequency specialists, with greens thought to be most acoustically sensitive between 200 and 700 hertz (Hz) (Ridgway *et al.* 1969). Because the hearing range of green turtles overlaps with the expected frequency range of the pile driving signals, NMFS considers it likely that greens can hear and respond to pile driving noise. Existing information also suggests that sea turtles rely more heavily on visual cues, rather than auditory, to initiate threat avoidance (Hazel *et al*. 2007).

Based on the description of the proposed action and on green turtle life history characteristics, post-recruitment juvenile and adult green turtles sheltering and foraging in Apra Harbor are the life stages most likely to be affected by the expected high intensity noise from pile driving. Because the green turtles found around Guam are likely to migrate widely between their preferred forage and nesting areas, the proposed action may affect greens from multiple NAs across a broad area of the south and western Pacific (Figure 2).

3.1.3 Threats to the Species

Global threats to green turtles are described in the 5-year review (NMFS & USFWS 2007a). The major threats to the species are alteration of nesting and foraging habitat, fishing bycatch, and direct harvest, which are briefly described below. Climate change also appears to be a growing threat to this species, and is also mentioned below.

Destruction and alteration of green turtle nesting and foraging habitats is occurring throughout the species' global range, especially through coastal development, beach armoring, beachfront lighting, vehicular/ pedestrian traffic, invasive species, and pollution from discharges and runoff. Under natural conditions, beaches can move landward or seaward with fluctuations in sea level. However, extensive shoreline hardening (e.g., seawalls) inhibits this natural process. Beach armoring is typically done to protect the coastal development from erosion during storms, but armoring blocks turtle nesting and often leads to beach loss. Coastal development also increases artificial lighting, which may disorient emerging hatchlings, causing them to crawl inland towards the lights instead of seaward. Coastal development also improves beach access for humans, resulting in more vehicular and foot traffic on beaches, causing compaction of nests and thereby reducing emergence success. Adult green turtles are opportunistic feeders, but are considered primarily herbivores that forage on seagrass and algae in shallow nearshore areas and coral reefs. Contamination from effluent discharges and runoff has degraded these habitats, and invasive species may reduce native algae species preferred by green turtles or could exacerbate susceptibility to, or development of disease (NMFS & USFWS 2007a; Guimaraes dos Santos *et al*. 2010).

Green turtles are susceptible to fisheries bycatch, particularly in nearshore artisanal fisheries. These fisheries use a diverse variety of gears, including long-lining, drift gillnets, set-nets, pound-nets, trawls, and others. Despite operating in the areas with the greatest density of adult green turtles, artisanal fisheries are typically the least regulated of all fisheries (NMFS & USFWS 2007a). Industrial fisheries such as the Hawaii-based deep-set and American Samoa longline fisheries also interact with green turtles, especially juveniles. Harvest of green turtles for their meat, shells, and eggs has been a major factor in the past declines of green turtles. Although reduced from previous levels, legal and illegal harvest of adults and eggs continues in most of the NAs described above, and remains a major factor in some parts of the species' range, including in the Marianas.

Although green turtles are probably beginning to be affected by impacts associated with anthropogenic climate change in several ways (described in more detail in the Environmental Baseline section below), no significant climate change-related impacts to green turtle populations have been observed to date. However, over the long-term, climate change-related impacts will likely influence biological trajectories in the future on a century scale (Parmesan and Yohe 2003). For example, increasing temperatures at nesting beaches may impact sex ratios of hatchlings (many rookeries already exhibit strong female bias [Binckley *et al*. 1998; Chan and Liew 1995; Godfrey *et al*. 1996; Godfrey *et al*. 1999; Godley *et al*. 2001; Kaska *et al*. 2006; Marcovaldi *et al*. 1997; Oz *et al*. 2004]) and/or increase embryonic mortality (Matsuzawa *et al*. 2002). Increased nest mortality has also been linked to erosion due to increased typhoon frequency (Van Houtan and Bass 2007) and intensity, which are predicted consequences of climate change (Webster *et al*. 2005). Seagrasses are a major food source for green turtles

worldwide. Seagrass habitats may suffer from decreased productivity and/or increased stress due to sea level rise and salinity and temperature changes (Short and Neckles 1999; Duarte 2002). Climate change induced shifts in ocean productivity linked to temperature changes (Harwood 2001; Edwards & Richardson 2004; Hays *et al*. 2005) may affect foraging strategies and therefore reproductive capacity for green turtles (Solow *et al*. 2002) similar to what has been observed during El Nino events in the western Pacific (Limpus and Nicholls 1994; Chaloupka 2001). While there is some available data on past trends, these data are limited, and current scientific methods are not able to reliably predict the future magnitude of climate change and associated impacts or the adaptive capacity of this species. Due to a lack of scientific data, the specific effects climate change will have on this species in the future are not predictable or quantifiable to any degree that would allow for more detailed analysis in this consultation (Hawkes *et al*. 2009). Based on the available information, climate change-related impacts are not considered significant within the context of the temporal scale of this action, as discussed further in the Environmental Baseline and Cumulative Effects sections below.

3.1.4 Conservation of the Species

Green turtles nesting in the US have benefited from both State and Federal laws passed in the early 1970s banning the harvest of turtles and their eggs. Protection and management activities since 1974 throughout the Hawaiian Archipelago and habitat protection at the French Frigate Shoals nesting area since the 1950's have resulted in increased population trends of both nesting and foraging turtles (Balazs and Chaloupka 2004). Elsewhere, the protection of nesting beaches against large-scale egg harvest appears to have reversed some downward nesting trends. Using long-term data sets, encouraging trends in green turtle nester or nest abundance over the past 25 years has become apparent in at least six locations including Hawaii, Australia, Japan, Costa Rica and Florida (Chaloupka *et al*. 2008a).

Efforts to reduce fisheries bycatch, such as the improvements made in the Hawaii-based longline fishery since the 1990s, has reduced green turtle interactions (NMFS & USFWS 2007a). Internationally, the conservation and recovery of green turtles is facilitated by a number of regulatory mechanisms at international, regional, national and local levels, such as the Food and Agricultural Organization of the United Nations (FAO) Technical Consultation on Sea Turtle-Fishery Interactions, the Inter-American Convention for the Protection and Conservation of Sea Turtles, the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), and others. As a result of these designations and agreements, many of the intentional impacts on sea turtles have been reduced: harvest of eggs and adults have been slowed at several nesting areas through nesting beach conservation efforts and an increasing number of community-based initiatives are in place to slow the take of turtles in foraging areas (Gilman *et al*. 2007; NMFS & USFWS 2007a).

3.2 Hawksbill Sea Turtles

Hawksbill turtles are distributed circumglobally, and can be found in the Pacific, Indian, and Atlantic Oceans, but not in the Mediterranean Sea, as described in the most recent hawksbill turtle 5-year status review (NMFS & USFWS 2007b). As shown above in Table 2, in 1978, all hawksbill turtles are listed as endangered under the ESA. Hawksbills are the most tropical sea turtle species, ranging from approximately 30° N latitude to 30° S latitude. They are closely associated with coral reefs and other hard-bottom habitats, but are also found in other habitats

including inlets, bays, and coastal lagoons. There are only five remaining nesting aggregations with more than 1,000 females nesting annually. These nesting aggregations are in the Seychelles, Mexico, Indonesia, and two in Australia (NMFS and USFWS 2007b). The global population has declined by more than 80 percent over the last three generations. Hawksbills face many of the same threats affecting green sea turtles. In addition, there continues to be a commercial market for hawksbill shell products, despite protections afforded to the species under U.S. law and international conventions (NMFS and USFWS 2007b).

3.2.1 Distribution and Abundance

Globally, most of the important hawksbill sea turtle nesting populations declined substantially during the 20th century. Hawksbill turtles are distributed across three major ocean basins; the Atlantic, the Indian, and the Pacific. More detail provided for the action area is located in Oceania, an area within the Pacific Basin.

Atlantic Ocean

In the western Atlantic, the largest hawksbill nesting population occurs on the Yucatán Peninsula of Mexico. Nesting also occurs in Antigua, Barbados, Costa Rica, Cuba, and Jamaica. Within the U.S., nesting occurs in Puerto Rico, the U.S. Virgin Islands, and along the southeast coast of Florida. At the two principal nesting beaches in the U.S. Caribbean where long-term monitoring has been carried out, populations appear to be increasing (Mona Island, Puerto Rico) or stable (Buck Island Reef National Monument, St. Croix, USVI) (NMFS and USFWS 2007b).

Indian Ocean

Of the approximately 83 nesting rookeries that have been identified for hawksbill sea turtles, 31 occur in the Indian Ocean. Many of those nesting areas are relatively small hosting 100 or fewer nesting females annually. However, some nesting rookeries in Madagascar, Iran, and Western Australia may have as many as 1,000 to 2,000 nesting females annually. Based on the number of nesting females the population trends at the 31 nesting rookeries over the recent past (last 20 years) have remained stable in two locations, declined at five, and are unknown for 24. Historically (20 to 100 years ago), population trends at these nesting rookeries were in decline at 17 sites and are unknown for 14 (NMFS and USFWS 2007b).

Pacific Ocean

Hawksbill turtles nest broadly in the Pacific, including on the islands and mainland of Southeast Asia, from China to Japan, and throughout the Philippines, Malaysia, Indonesia, Papua New Guinea (PNG), the Solomon Islands, and Australia, with the largest nesting concentration occurring on remote islands in the GBR area. However, along the eastern Pacific Rim where nesting was common in the 1930s, hawksbills are now rare or absent (NMFS and USFWS 2007b). Hawksbill nesting information is available for eight locations within Oceania: GBR, PNG, Solomon Islands, Vanuatu, Fiji, Micronesia (Federated States of Micronesia (FSM) and Palau), the Samoan Islands (Western Samoa and American Samoa), and the Mariana Islands. Hawksbill nesting may occur elsewhere within the range of this population, but little to no information is available, and nesting activity at those sites is thought to be very low. Based on the best information currently available, about 5,400 to 6,100 hawksbill turtles nest annually in Oceania, (NMFS 2010a) and the overall trend is downward (NMFS & USFWS 2007b).

Mariana Archipelago

Sub-adult and adult hawksbill turtles occur in low abundance in nearshore waters around the Mariana Islands (NMFS & USFWS 2007b). In CNMI, they have been sighted as far north as Anatahan (Ilo *et al.* 2005) and sporadically around Farallon de Medinilla (Kolinski *et al*. 2004; Ilo and Manglona 2002). They are occasionally observed by divers in the waters of Saipan, and two hawksbills were captured there in 2009 during the in-water monitoring program (CNMI DFW 2009). Hawksbills are also infrequently sighted around Rota (Kolinski *et al*. 2004; Ilo *et al.* 2005). No nesting trend data are available for the CNMI. Although anecdotal information suggests that hawksbill nesting occurred in the CNMI in the past, no nesting activity has been documented in recent years (CNMI DFW unpublished annual reports to PIRO).

Grimm and Farley (2008) report that hawksbills are frequently sighted in the nearshore waters surrounding Guam. However, they are less common than green sea turtles (NMFS and USFWS 2007b). According to Wiles *et al.* (1995), hawksbills represent about 13% of turtles sighted around Guam. Based on this and the estimated 150 to 250 green turtles present, NMFS estimates that about 22 to 37 hawksbills reside year-round in the nearshore waters around Guam. Between 5 and 10 hawksbills are estimated to nest annually at Guam, and although trend data are lacking, the population is thought to be declining (NMFS & USFWS 2007b). The first reported hawksbill turtle nest on Guam was in November 1991 (NMFS & USFWS 1998b) and in 1997 a possible hawksbill nest was reported from a beach at Sumay Cove (Grimm and Farley 2008). In 2008, four nesting attempts at Adotgan Dikiki (Spanish Steps) were attributed to a hawksbill turtle (Grimm and Farley 2008).

3.2.2 Life History Characteristics Affecting Vulnerability to Proposed Action

As with green turtles, hawksbills hatch at their natal beaches, hatchlings spend several years of early development in the oceanic (pelagic) zone. At about 35 cm carapace length, juveniles recruit to coastal areas where post-recruitment juveniles and adults forage and mature in shallow coastal areas, feeding primarily on sponges, but also on other benthic invertebrates, coral, and algae. When on their foraging grounds, post-recruitment hawksbill turtles are often referred to as "residents". The majority of sea turtles in coastal areas spend their time at depths <5 m below the surface (Schofield *et al.* 2010, Hazel *et al.* 2009). Upon reaching sexual maturity, adult hawksbills typically undertake long migrations between their resident foraging grounds and their natal nesting areas, where they mate and females nest. As with greens, nesting females are referred to as "nesters", which distinguishes them from "resident" turtles that regularly forage in that area. Although males also make mating migrations, because they do not crawl out on the beach as the females do, those males are nearly impossible to distinguish from the resident males.

As with green turtles, hawksbill forage grounds and natal nesting areas are frequently located in different island groups, and residents at a given island group may originate from multiple natal nesting areas. Thus, upon maturation, adult hawksbills undertake long migrations between their resident foraging grounds and their natal nesting areas (NMFS & USFWS 2007b). Two post-nesting hawksbills were fitted with satellite tags on Tutuila, American Samoa; one migrated several hundred km to Western Samoa, and the other migrated more than 1,000 km to the Cook Islands (Tagarino *et al*. 2008). Post-nesting hawksbills on the GBR are reported to migrate more

than 2,000 km (Miller *et al*. 1998). Currently, post-nesting tracking information is unavailable for Guam's hawksbills.

Research into turtle hearing is limited, and no specific information is available for hawksbills. However, based on the similarity in hearing between greens and loggerheads, and the hawksbill's close taxonomic relationship to these species, NMFS considers it likely that hawksbill hearing is also similarly specialized for low frequencies. As described above, green turtles are thought to be most acoustically sensitive between 200 and 700 Hz (Ridgway *et al.* 1969). Loggerhead (*Caretta carreta*) hearing is very similar to that of greens, being most sensitive between 250 and 1,000 Hz (Bartol *et al*. 1999). Because the hearing range of hawksbill sea turtles likely overlaps with the expected frequency range of the pile driving signals, NMFS considers it likely that hawksbills can hear, and respond to pile driving noise. Existing information about sea turtle sensory biology also suggests that sea turtles rely more heavily on visual cues, rather than auditory, to initiate threat avoidance (Hazel *et al*. 2007).

Based on the description of the proposed action and on hawksbill turtle life history characteristics, post-recruitment juvenile and adult hawksbill turtles sheltering and foraging in Apra Harbor are the life stages most likely to be affected by the expected high intensity noise from pile driving. Because the hawksbill turtles found around Guam are likely to migrate widely between their preferred forage and nesting areas, the proposed action may affect hawksbills from multiple NAs across a broad area of the south and western Pacific.

3.2.3 Threats to the Species

Global threats to turtles are described in the 5-year review. As discussed for green turtles (Section 3.1.3), destruction and alteration of habitat, as well as direct harvest are considered the major threats to hawksbills. Climate change also appears to be a growing threat. Destruction and alteration of hawksbill nesting and foraging habitats is occurring throughout the species' global range, especially through coastal development, beach armoring, beachfront lighting, vehicular/ pedestrian traffic, invasive species, and pollution from discharges and runoff. The adverse impacts of these threats described for greens, are virtually the same for hawksbills (NMFS & USFWS 2007b), so they are not repeated here. Although hawksbills interact with some fisheries, their bycatch rates are much lower than for the other sea turtle species, particularly with industrial fisheries.

Harvest of hawksbill shells and eggs continues to be a major threat. Due to the beauty of their shells, hawksbill adults may be harvested more heavily than other sea turtle species. Despite protections under CITES, the "tortoiseshell" trade continues in many areas. As with other sea turtle species, egg harvest continues unabated in parts of the Pacific, including Southeast Asia, Melanesia, and Polynesia (NMFS & USFWS 2007b). Kinch (2007) estimates that about 250 hawksbill turtles are sold annually in Port Moresby, but this may represent only a small fraction of the overall subsistence and semi-commercial take of hawksbills in PNG. It is estimated that large numbers of hawksbill turtles from Australian rookeries are being harvested in neighboring countries including Indonesia, PNG, Solomon Islands and Fiji to supply meat and/or tortoiseshell for use locally or for export.

Although green turtles are probably beginning to be affected by impacts associated with anthropogenic climate change in several ways (described in more detail in the Environmental Baseline section below), no significant climate change-related impacts to hawksbill turtle populations have been observed to date. However, over the long-term, climate change-related impacts will likely influence biological trajectories in the future on a century scale (Parmesan and Yohe 2003). In the future, climate change-related increasing temperatures, sea level rise, changes in ocean productivity, and increased frequency of storms events are all potential threats to hawksbills for the same reasons described above for green turtles. Additionally, because hawksbills typically inhabit coral reef communities, they are vulnerable to changes that affect these communities, such as increased bleaching events, increased occurrence of disease, and weakening of coral skeletons that may result from global climate change (McWilliams *et al.* 2005; Langdon *et al.* 2000; Ohde and Hossain 2004). As with green turtles, only limited data are available on past trends, and current scientific methods are not able to reliably predict the future magnitude of climate change and associated impacts or the adaptive capacity of this species. Due to a lack of scientific data, the specific future effects climate change will have on this species are not predictable or quantifiable to any degree that would allow for more detailed analysis in this consultation (Hawkes *et al.* 2009). Based on the available information, climate change-related impacts are not considered significant within the context of the temporal scale of this action, as discussed further in the Environmental Baseline and Cumulative Effects sections below.

3.2.4 Conservation of the Species

Numerous conservation programs are being implemented around the world to protect nesting habitat and reduce harvesting and fisheries bycatch of all sea turtle species, and numerous regulatory mechanisms are in place at international, regional, national and local levels to protect sea turtles (Section 3.1.4 above). Many of these programs likely benefit hawksbills. However, hawksbills continue to decline rapidly in the Pacific and Indian Ocean areas (NMFS & USFWS 2007b).

4 Environmental Baseline

The environmental baseline for a biological opinion includes: past and present impacts of all State, Federal, or private actions and activities in the action area; the anticipated impacts of all proposed Federal projects in the action area that have already undergone Section 7 consultation; and the impact of State or private actions which are contemporaneous with the consultation in process (50 CFR 402.02). The Consultation Handbook further clarifies that the environmental baseline is an analysis of the effects of past and ongoing human and natural factors leading to the current status of the species, its habitat (including designated critical habitat), and ecosystem, within the action area (USFWS & NMFS 1998). The purpose of describing the environmental baseline in this manner within a biological opinion is to provide the context for the effects of the proposed action on the listed species. As described in Section 2 above, the action area for this consultation consists of the nearshore waters within 25 kilometers of Apra Harbor on Guam, (Figures 1 and 4). The past and present impacts of human and natural factors leading to the status of green and hawksbill sea turtles within the action area include coastal development, fishing interactions, vessel strikes, direct take, marine debris, and climate change.

Guam is a small tropical island of volcanic origin that is surrounded by coral reefs. It is the southernmost island in the Marianas, and with a land area of 210 miles^2 (544 km^2), it is also the largest. The island is about 30 miles (48 km) long, with about 78 miles (125.5 km) of shoreline. The northern third of the island consists of a relatively flat coralline limestone plateau with steep coastal cliffs and narrow coastal plains. Low hills in the center, give way to mountains in south, where the highest point, 1,332 ft (406 m) Mt Lamlam is located.

The Central Intelligence Agency World Factbook estimated the island's population at 183,286 in June 2011, with an estimated growth rate of 1.314% (CIA 2011). Additionally, components of the Guam and CNMI Military Relocation project, which is expected to result in the relocation of Marines from Okinawa and other military build-up projects on Guam, has been underway since 2010. Based on the information in the Final Environmental Impact Statement for that action (USN 2010a), the relocation could temporarily increase the population by about 79,000 people during the projected 2014 construction peak, and stabilize at about 33,000 additional people permanently moved to Guam by 2020.

Portions of the nearshore marine environment around Guam have been degraded by impacts from: intense combat during World War II (WWII); shoreline development; sediment-laden runoff; and pollution from run-off and years of poorly treated wastewater effluent. Apra Harbor is a natural deep-water harbor, which has been heavily modified, particularly since World War II (Figure 3).

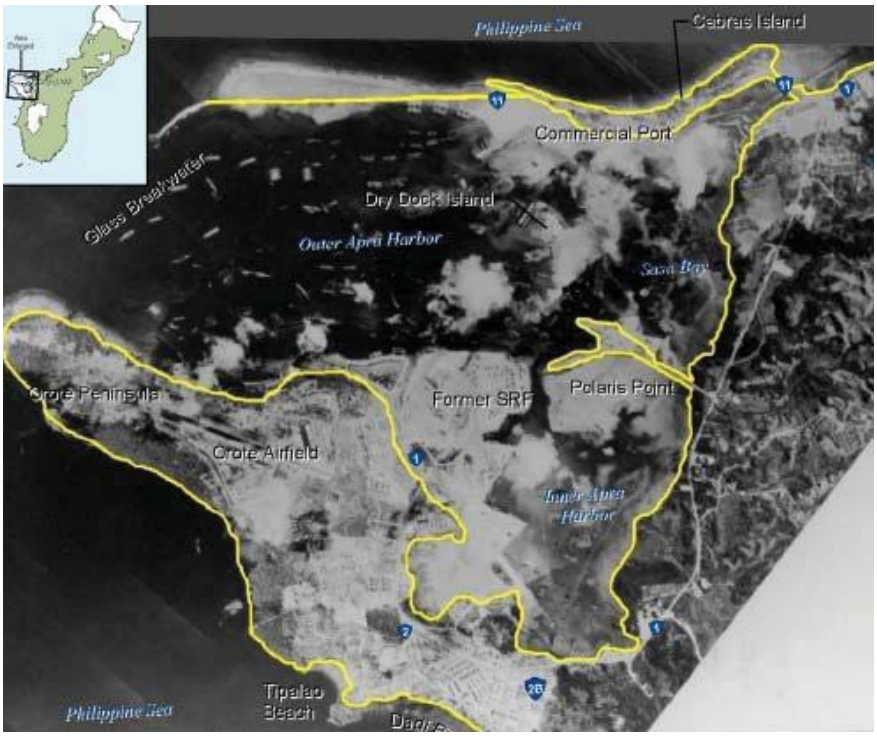

Figure 3. Apra Harbor July 1945. The yellow line indicates the approximate shoreline prior to the dredging and fill projects of the 1940s (USN 2011).

Much of the harbor's current topography and bathymetry is manmade; the result of work begun by the US Government in 1943. Extensive dredging and fill projects resulted in the creation of Inner Apra Harbor and its channel. Other fill projects resulted in the creation of Dry Dock Peninsula, Polaris Point, and the manmade northeastern and southeastern shorelines, and the Glass Breakwater, which extends from Cabras Island, out and across Luminau Reef to provide increased protection for the harbor. Other impacts include the knolls (hard bottom sites that protrude at least 25 ft (7.6 m) above the harbor bottom) that were explosively cleared during WWII, because they were considered navigational

hazards. Some of the shallower knolls have been used as anchorage sites since WWII, and some are still used by military and commercial vessels. Sunken ships rest on the sea floor at several locations throughout the harbor, as does metallic wreckage and other debris. The east end of Apra Harbor is highly developed and brightly illuminated at night. As viewed from Spanish Steps, which is located approximately 4,600 meters west of Polaris Point, industrial facilities light-up a broad swath across the east end of the harbor; with the commercial port and Cabras Island power plant area on the north side, the Naval Station to the south, and some residential lighting also visible on the hills between (USN 2010b). The existing lights from the commercial port are particularly bright and clearly visible to nesting turtles and hatchlings in the water, and on the beach, at Spanish Steps. The lights of the Naval Station are not quite as bright, but some areas are also clearly visible. It is probable that existing harbor lighting is currently having adverse impacts on green and hawksbill reproductive success at Spanish Steps. Other on-going activities that may impact sea turtles in Apra Harbor include period maintenance dredging as well as repair and maintenance of existing seawalls and wharves at both the Naval Station and at the Guam commercial port. In addition to the increased population mentioned above, the Navy's proposed build-up would also result in construction and maintenance dredging, the oversheeting of four wharves, and the construction of a new carrier pier. This work would be done at the east end of the outer harbor as well as within in inner Apra Harbor. NMFS completed formal consultation with the Navy for the proposed build-up on August 25, 2010, and determined that the proposed action would not jeopardize any ESA-listed marine species (NMFS 2010b).

Based on information presented in the Navy's BA, Apra Harbor's turtle habitats and turtle presence can be described as a continuum. The eastern end of the harbor, including Sumay Cove, is highly disturbed. Although corals, algae, and sponges that may serve as turtle forage are found in the area, benthic resources typically increase in number, size, and diversity as one travels from east to west. Data is limited, but turtle sightings also tend to increase along the same continuum, with turtles being rare in the inner harbor, and occasionally present east of Big Blue and Western Shoals. Turtles appear to occur in low numbers but are frequently seen on the west sides of these shoals, and they appear to become increasingly common toward the mouth of the harbor, where low-level green turtle nesting continues on the beaches below Spanish Steps, and hawksbill crawls have recently been observed. Low numbers of turtles are also observed in Sasa Bay, east to northeast of Polaris Point, where sponges, macro algae, and sea grass provide forage resources.

Nearshore fisheries on Guam consist primarily of subsistence fishing, but there are also small-scale commercial fisheries for coral reef and pelagic species. Contemporary methods include: boat-based and land-based hook-and-line fishing (handline or rod-and-reel), net fishing (cast, gill, drag, and surround net), spear fishing, hook and gaff, and gleaning (Hensley and Sherwood 1993). Nearshore fisheries occasionally result in entanglement and drowning of sea turtles. Gillnets are the most problematic for turtles, because the nets are left untended, and entangled animals usually drown. Hook-and-line fishing also hooks or entangles turtles, but the chance of survival is higher than if caught in a gillnet. In a study of stranded green turtles in Hawaii (stranded turtles are injured, sick, or dead turtles found on shore), the second and third most common known causes of stranding were fishing related. Hook-and-line fishing gear-induced trauma accounted for 7%, and gillnet fishing gear-induced trauma was responsible for 5% (Chaloupka *et al*. 2008b). However, most turtles drowned in fishing gear probably sink rather

than strand, making it very difficult to estimate the total number of green turtles killed annually by nearshore fishing interactions, even in Hawaii where turtles are much better monitored and studied than in the Marianas (NMFS 2008).

Hazel *et al*. (2007) report that vessel collision is a significant source of anthropogenic mortality for marine turtles. Based on Hawaii data for the period of 1998 to 2007 (NMFS 2008), the estimated total number of green turtles killed annually by boat collisions in the Main Hawaiian Islands (MHI) was between 25 and 50. The number of hawksbills similarly killed was much lower; between 0.2 and 0.4 turtles annually. The nearshore densities of boats and turtles are much lower around Guam than in Hawaiian nearshore waters, thus the number of green and hawksbill turtles killed annually by boat collisions around Guam is likely much lower. Although little information exists to quantify this impact, vessel collision has been implicated as the cause of three green turtle strandings in Apra Harbor between November 2002 and April 2008 (DAWR unpublished data).

Direct take through harvest of turtles and their nest continues on Guam and the other inhabited islands of the Mariana Archipelago, however, few data are available to quantify this impact. Vogt (2009) reported obvious poaching activity of nests on Tinian during surveys in 2007. During the 2009 nesting season on Saipan, three out of what is thought to be a total of five nesting turtles were poached as were three nests (DFW 2009). On Guam, DAWR has responded to 17 poachings of greens and 1 hawksbill since 1975 (S. Wusstig personal comm.).

Marine debris continues to accumulate in the ocean and along shorelines within the action area. Turtles may become entangled and drown, and ingested trash may cause intestinal blockage and death. Between October 2004 and September 2008, the American Samoa Department of Marine and Wildlife Resources (DMWR) necropsied 4 green turtles that stranded on Tutuila. Two of those turtles had plastic and aluminum in their guts (Tagarino *et al*. 2008). However, because only a small percent of dead or dying sea turtles strand, little information is available to adequately quantify the impacts on green and hawksbill turtles that may result from ingestion of marine debris. Although no documentation is available to describe ingestion for turtles on Guam, it is reasonable to expect that turtles here and elsewhere are equally likely to ingest marine debris they encounter as are turtles in American Samoa. Accumulated marine debris on nesting beaches can also impede nesting success by altering nest excavation and through potential entrapment of hatchlings under debris that is inadvertently buried over them when the nesting female covers the clutch. For example, the nesting beaches at Spanish Steps (southwestern Apra Harbor) are heavily impacted by accumulated marine debris.

The global mean temperature has risen 0.76°C over the last 150 years, and the linear trend over the last 50 years is nearly twice that for the last 100 years (Solomon *et al.* [eds] 2007). Because climate change is a global phenomenon, resultant impacts have likely been occurring in the action area although scientific data describing any impacts that have occurred from climate change in the action area are lacking. As discussed in the Threats Section, climate change is likely beginning to affect sea turtles found in the action area through the impacts of rising sand temperatures, rising sea level, increased typhoon frequency, and changes in ocean temperature and chemistry.

While sex ratios vary naturally within and among seasons and nesting locations, several species already exhibit female bias throughout their major rookeries worldwide (Chan and Liew 1995; Godfrey *et al.* 1996; Marcovaldi *et al.* 1997; Binckley *et al.* 1998; Godfrey *et al.* 1999; Godley *et al.* 2001; Oz *et al.* 2004; Kaska *et al.* 2006). Monitoring data over a long enough timescale to discern climate change related trends in sex ratio have not been collected in the action area. Sea level rose approximately 17 cm during the 20th century (Solomon *et al.* [eds] 2007) and further increases are expected. There are several predictions for potential future sea turtle nesting habitat loss due to sea level rise (Fish *et al.* 2005; Baker *et al.* 2006; Fuentes 2009). However, available data are insufficient to determine an existing correlation between past sea level rise and sea turtle population dynamics (Van Houtan 2010).

Global climate change-induced elevated temperatures, altered oceanic chemistry, and rising sea level may be contributing to changes to coral reef and seagrass ecosystems (as described above in Status of the Species) which provide resting and foraging habitat for green and hawksbill sea turtles, although it is difficult to distinguish impacts of climate-related stresses from other stresses that produce more prominent short term effects (Parry *et al.* [eds] 2007). Climate change-induced shifts in ocean productivity linked to temperature changes (Harwood 2001; Edwards & Richardson 2004; Hays *et al.* 2005) may affect foraging strategies and therefore reproductive capacity for sea turtles (Solow *et al.* 2002; Chaloupka *et al.* 2008a), similar to what has been observed during El Nino events in the Pacific (Limpus and Nicholls 1994; Chaloupka 2001; Saba *et al.* 2007; Reina *et al.* 2008). These shifts in abundance of foraging resources are also directly linked to observed modifications in phenology for sea turtles such as longer re-migration intervals and temporal shifts in nesting activity (Weishampel *et al.* 2004; Hawkes *et al.* 2007). However, at this time it is only possible to speculate as to the implications of such impacts, as findings raise numerous follow up questions (listed by Weishampel *et al.* 2004) including whether earlier nesting will affect overall fecundity, clutch size, incubation length, hatch success, hatchling survivorship, food availability for hatchlings, mating synchrony, and sex ratio. Changes in reproductive capacity and temporal shifts of nesting activity associated with changing environmental conditions have not been studied specifically in the action area.

Additional potential effects of climate change on sea turtles include range expansion and changes in migration routes (Robinson *et al.* 2008). Leatherbacks have extended their range in the Atlantic north by 330km in the last 17 years as warming has caused the northerly migration of the 15°C sea surface temperature (SST) isotherm, the lower limit of thermal tolerance for leatherbacks (McMahon and Hays 2006). Similar studies have not been done for the green and hawksbill sea turtles that may be adversely affected in the action area. As such, scientific data are lacking on changes in migration routes of these sea turtles. Therefore, it is not possible to say with any degree of certainty whether and how their migration routes and ranges have been or are currently being affected.

Causal attribution of recent biological trends to climate change is complicated because non-climatic influences dominate local, short-term biological changes. However, the meta-analyses of 334 species and the global analyses of 1,570 species show highly significant, nonrandom patterns of change in accord with observed climate warming in the twentieth century. In other words, it appears that these trends are being influenced by climate change-related phenomena, rather than being explained by natural variability or other factors (Parmesan & Yohe 2003). The

details discussed previously in this section support the probability that recently observed changes in sea turtle phenology, sex ratio, and foraging characteristics in studied populations may be influenced by climate change-related phenomena. However, the implications of these changes are not clear in terms of population level impacts, and data specific to the action area are lacking. Therefore, as stated earlier, recent impacts from climate change in the action area are believed to be insignificant at this time.

5 Effects of the Action

In this section of a biological opinion, NMFS assesses the probable effects of the proposed action on threatened and endangered species. Effects of the Action refers to the direct and indirect effects of an action on the species or critical habitat, together with the effects of other activities that are interrelated or interdependent with that action that would be added to the environmental baseline. Indirect effects are those that are likely to occur later in time (50 CFR 402.02). The effects of the action are considered within the context of the Status of Listed Species and Environmental Baseline sections of this Opinion to determine if the proposed action can be expected to have direct or indirect effects on threatened and endangered species that appreciably reduce their likelihood of surviving and recovering in the wild by reducing their reproduction, numbers, or distribution (50 CFR 402.02), otherwise known as the jeopardy determination.

Approach. NMFS determines the effects of the action using a sequence of steps. The first step identifies potential stressors associated with the proposed action with regard to listed species. NMFS may determine that some potential stressors result in insignificant, discountable, or beneficial effects to listed species, in which case these potential stressors are considered not likely to adversely affect listed species, and subsequently are considered no further in the opinion. Those stressors that are expected to result in significant negative (i.e., adverse) effects to listed species are analyzed via the second, third, and fourth steps described below.

The second step identifies the magnitude of the stressors (e.g., how many individuals of a listed species would be exposed to the stressors; *exposure analysis*). In this step of our analysis, we try to identify the number, age (or life stage), and gender of the individuals that are likely to be exposed to a proposed action's effects, and the populations or subpopulations those individuals represent.

The third step describes how the exposed individuals are likely to respond to the stressors (*response analysis*). In this step, NMFS determines if the stressors are likely to result in any of the components of take as defined under the ESA (e.g., harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect or attempt to engage in any such conduct).

The final step in determining the effects of the action is to establish the risks those responses pose to listed resources (*risk analysis*). The risk analysis is different for listed species and designated critical habitat. However, the action area does not include proposed or designated critical habitat, thus it is not considered in this opinion. Our jeopardy determinations must be based on an action's effects on the continued existence of threatened or endangered species as those "species" have been listed, which can include true biological species, subspecies, or distinct population segments of vertebrate species. Because the continued existence of listed species depends on the fate of the populations that comprise them, the viability (probability of

extinction or probability of persistence) of listed species depends on the viability of their populations. Thus, because green and hawksbill turtles are globally listed, and these species consist of nesting aggregations, this final step first determines the risk posed by the proposed action to affected nesting aggregations, then relates that risk to the listed species.

5.1 Stressors

The following 7 potential stressors may occur due to the proposed action: exposure to elevated noise levels; collision with vessels; direct impact by heavy equipment; disturbance from human activity and equipment operation; loss or degradation of sheltering and forage habitat; exposure to elevated turbidity; and exposure to wastes and discharges. NMFS has reviewed each of the stressors to determine if their effects are expected to be significant (e.g. size of the impact), discountable (how likely it is to occur), or beneficial (positive effect). Those that are insignificant, extremely unlikely to occur, or beneficial will not be discussed further in this opinion.

5.1.1 Elevated Noise Levels

The proposed action is expected to result in about 180 8-hour days (about 30 6-day workweeks) of high-intensity in-water noise due to pile driving. Exposure to this noise may impact turtle hearing and may drive turtles away from sheltering and foraging habitats located at or near the proposed project site. These impacts are considered adverse effects. Because the potential for adverse effects from this stressor is considered greater than discountable, the effects of these impacts will be addressed below in the exposure-response-risk analyses.

5.1.2 Collision with vessels

Sea turtles must surface to breathe, and they are known to rest or bask at the surface. Therefore, when at or near the surface, they are at risk of being struck by vessels or their propellers as the vessels transit to and from the project site. Potential injuries and their severity will depend on the speed of the vessel, the part of the vessel that strikes the animal, and the body part impacted. Injuries from boat strikes may include bruising, broken bones or carapaces, and lacerations. The recovery plan for green sea turtles indicates that boat collision is a major threat around the MHI. Although not identified as a significant risk for either species in the Marianas, the recovery plans for both turtle species suggest that the incidence of collision is expected to increase as vessel size, speed, and traffic density increases, or as animal density increases (NMFS & USFWS 1998a & b).

Existing information about sea turtle sensory biology suggests that sea turtles rely more heavily on visual cues, rather than auditory, to initiate threat avoidance. Research also suggests that sea turtles can not be expected to consistently notice and avoid vessels that are traveling faster than 2 nautical miles per hour (Hazel et al. 2007). Consequently, vessel operators must be responsible to actively watch for and avoid sea turtles, and to adjust their speed based on expected animal density and on lighting and turbidity conditions to allow adequate reaction time to avoid marine animals. Based on the limited number of trips expected, the understanding that vessel operations will be primarily limited to Apra Harbor, and on the expectation that the vessels will operated in accordance with the conservation measures for this action (USN 2011) that require operators to watch for and avoid protected species, and to operate vessels at reduced speeds NMFS considers

that the risk of collisions between action-related vessels and green and hawksbill turtles is discountable, and this stressor will be discussed no further in this opinion.

5.1.3 Direct Impact by Heavy Equipment

Sea turtles could conceivably be struck by pile driving equipment or an anchor if they were below either of those pieces of equipment. Potential injuries and their severity would depend on the animal's proximity to the bottom when struck, the angle of the strike, and the body part impacted. Injuries may include cuts, bruises, broken bones, cracked or crushed carapaces, and amputations, any of which could result in the animal's death. However, the proposed work would be a relatively stationary activity, that is restricted a relatively small area. Sea turtles must be directly beneath the equipment in order to be injured or killed by direct impact. Few sea turtles are expected to be within Sumay Cove under undisturbed conditions, and they are likely to avoid the area due to the high level of in-water noise and human activity. Also, the applicant has committed to watch for turtles, starting 30 minutes prior to commencing work, with work being postponed or halted when turtles are within 46 m (50 yards). Based on the information above, NMFS believes that sea turtles are capable and likely to avoid the area, and we are unaware of any information that contradicts that judgment. As such, we have determined that the likelihood of a sea turtle being adversely injured or killed by direct impact with heavy equipment is discountable, and this stressor will be discussed no further in this opinion.

5.1.4 Disturbance from Human Activity and Equipment Operation

This stressor refers to construction-related disturbances other than exposure to elevated noise levels. Exposure to construction activities may startle sea turtles should they encounter them. Sea turtle density is considered low in the proposed construction area, and turtles typically avoid human activity around Guam where direct take (poaching) continues. Based on this, the most likely effect of this interaction would be an avoidance behavior leading to the animal rapidly leaving the project area without injury. Additionally, the contractor would reduce the likelihood of this interaction by watching for and avoiding sea turtles before commencing work and by postponing or halting operations when protected species are within 46 m (50 yards). Based on the information above, we expect that disturbances from human activity and equipment operation would be infrequent and non-injurious, resulting in insignificant affects on green and hawksbill turtles. As such, this stressor will be discussed no further in this opinion.

5.1.5 Loss or Degradation of Sheltering and Forage Habitat

The proposed 18-inch oversheeting of the existing seawall would permanently remove about 139 m^2 (1,500 ft^2) of benthic habitat in Sumay Cove. The channel floor consists primarily of sand and unconsolidated sediments; the result of dredge-and-fill operations that created the current shorelines. The seawall to be oversheeted is covered by hermatypic and soft corals, turf algae, sponges, and tunicates. About 37% of sea floor within 2 m of the seawall is covered by soft corals (USN 2011); likely growing on substrate provided by debris. Although low numbers of sea turtles may utilize this habitat, higher value habitat is readily available on the shoals and reef areas immediately north and west of the channel entrance. Because the area of lost habitat would be small and is highly impacted, and because high value habitat is readily available nearby, we expect that the loss of sheltering and forage habitat due to this action would have insignificant effects on green and hawksbill turtles, and as such will be discussed no further in this opinion.

5.1.6 Increased Turbidity

Green and hawksbill sea turtles are often found in turbid waters. Since sea turtles breathe air instead of water, exposure to increased turbidity should not adversely affect their respiration or other biological functions. Although it is impossible to predict how individual animals might react to plumes of elevated turbidity, some turtles may avoid dense turbidity plumes in favor of clearer water. The Navy's contractor would be required to install silt curtains around in-water work to minimize the movement of sediments mobilized by that work. Additionally, all backfill would be done behind the newly-installed sheet piles, which should virtually eliminate increase turbidity from that component. Thus, we expect that turbidity plumes would be small (limited to the area immediately adjacent to the work) and virtually undetectable outside of the silt curtains. Based on the expectation that areal avoidance due to pile driving and other activities would be greater than the extent of detectable plumes of elevated turbidity, NMFS considers it unlikely that any sea turtles would approach close enough to the work area to be exposed to project-related elevated turbidity. Based on this information, we expect that exposure to elevated turbidity would have insignificant impacts on sea turtles, and this stressor will be discussed no further in this opinion.

5.1.7 Wastes and Discharges

Construction wastes may include plastic trash and bags that may be ingested and cause digestive blockage or suffocation, or if large enough, along with discarded sections of ropes and lines, may entangle marine life. Equipment spills, discharges, and run-off from the project area could contain hydrocarbon-based chemicals such fuel oils, gasoline, lubricants, hydraulic fluids and other toxicants, which could expose protected species to toxic chemicals. Depending on the chemicals and their concentration, the effects of exposure may range between animals temporarily avoiding an area, to death of the exposed animals. Local and Federal regulations prohibit the intentional discharge of toxic wastes and plastics into the marine environment. Additionally, the Navy has incorporated into their proposed action conservation measures that include measures intended to prevent the introduction of wastes and toxicants into the marine environment (USN 2011). Based on the information above, we expect that construction-related discharges and spills would be infrequent, small, and quickly cleaned if they do occur. Therefore, we have determined that exposure to construction-related wastes and discharges would result in insignificant effects on green and hawksbill turtles, and this stressor will be discussed no further in this opinion.

In summary, 1 of the 7 stressors associated with the proposed action is considered likely to adversely affect green and hawksbill turtles (exposure to elevated noise levels). This stressor is addressed in the exposure-response-risk analyses below. The other 6 stressors (collision with vessels, direct impact by heavy equipment, disturbance from human activity and equipment operation, loss or degradation of sheltering and forage habitat, exposure to increased turbidity, and exposure to wastes and discharges) were determined to be not likely to adversely affect sea turtles and are addressed no further in this opinion.

5.2 Exposure

This section analyzes the proposed action's potential for exposing green and hawksbill sea turtles to adverse levels of sound energy during pile driving operations.

5.2.1 Exposure to Elevated Noise Levels during Pile Driving

This analysis is based on the pile type, the method of driving, the expected substrate, and the duration of work as described in the June 1, 2011, BA (USN 2011) and the expected source levels for similar pile driving actions, based on the California Department of Transportation's (CALTRANS) Compendium of Pile Driving Sound Data (Compendium) (CALTRANS 2007). The exposure analysis is organized as follows:

1: Estimate the in-water source level for the pile type.

2: Estimate the ranges where in-water sound energy would fall to current thresholds for expected effects.

3: Estimate the number of green or hawksbill sea turtles potentially exposed to adverse levels of sound energy.

5.2.1.1 Estimate the in-water source level for each piling type:

As described in Section 2, the project would include about 180 8-hour workdays to impact drive about 1,000 linear feet of 24-inch (61 cm) wide steel sheet pilings, and 55 16.5-inch octagonal concrete pilings.

Acoustics Background. Sound can be measured and quantified in several ways, but the logarithmic decibel (dB) is the most commonly used unit of measure, and sound pressure level (SPL) is a common and convenient term used to describe intensity. In water, sound pressure is typically referenced to a baseline of 1 micropascal (re 1 μPa), vice the 20 μPa baseline used for in-air measurements. Consequently, 26 dB must be added to an in-air measurement to convert to an appropriate in-water value for an identical acoustic source (Bradley and Stern 2008). To assess the potential impact of a sound on marine resources, NMFS often assesses impacts based on the root-mean-square (dB_{rms}) of an acoustic pulse. This is the portion of a pulse that contains 90% of the sound pressure. For brevity, all further references to SPL assume dB_{rms} re 1 μPa, unless specified differently.

Sound Transmission in Water. Transmission loss (attenuation of sound intensity over distance) varies according to several factors in water, such as water depth, bottom type, sea surface condition, salinity, and the amount of suspended solids in the water. Sound energy dissipates through mechanisms such as spreading, scattering, and absorption (Bradley and Stern 2008). Spreading refers to the apparent decrease in sound energy at any given point on the wave front because the sound energy is spread across an increasing area as the wave front radiates outward from the source. In unbounded homogenous water, sound spreads out spherically, loosing as much as 7 dB with each doubling of range. Toward the other end of the spectrum, sound may expand cylindrically when vertically bounded such as by the surface and substrate, losing only about 3 dB with each doubling of range. In addition to spreading, sound energy can be lost through scattering and absorption. Scattering refers to the sound energy that leaves the wave front when it "bounces" off of an irregular surface or particles in the water. Absorption refers to the energy that is lost through conversion to heat due to fiction. Irregular substrates, rough surface waters, and particulates in the water column increase scattering loss, while soft substrates, such as mud and silt increase absorption loss. The relatively shallow nearshore waters of most harbors and marinas, such as Sumay Cove and Apra Harbor with their irregular bottoms and high levels of silt and mud, are considered poor environments for acoustic

propagation because sound typically dissipates more rapidly under those conditions than in open waters.

Accurately predicting received noise levels at a given range (isopleth) requires complex equations and detailed information that is rarely available. Typically, predictions are made by estimating spreading loss based on the equations RL = SL – 20LogR, for spherical spreading, and RL = SL – 10LogR for cylindrical spreading (RL = received level; SL = source level; and R = range in meters (m)). Actual spreading loss is thought to be somewhere between the two, with absorption and scattering increasing the loss. In the absence of site specific transmission loss data, the practical spreading loss equation, RL = SL – 15LogR, is often used to estimate the RL for actions in shallow nearshore marine environments. That formula was used in this analysis to account for the acoustic environment expected within Sumay Cove and Apra Harbor. Outside of Apra Harbor, the sea floor drops away quickly and transmission loss likely approaches that of spherical spreading.

Pile Driving Noise. The in-water SL is the sound energy at 1 m from the source. The SL of impact pile driving is typically high, sometimes in excess of 200 dB (CALTRANS 2007). Frequencies vary according to several factors, including the pile type, the substrate, and the intensity of impact. The SL is also affected by pile type and the substrate (typically, the harder and larger the piling, the louder; the harder the bottom, the louder), as well as the impact energy (the harder the impact, the louder). However, measured sound levels for individual pile driving events may vary over time. Signal analysis of impact-driving sheet piles indicates a relatively broadband signal with most of the energy between 25 and 4,000 Hz, whereas concrete piles have a signature with two components; a low frequency peak at about 200 Hz and high frequency broadband signal between 1,000 and 3,000 Hz (CALTRANS 2007).

Neither the Navy nor NMFS has site-specific noise measurements for pile-driving in Apra Harbor. Consequently, both agencies referred to the CALTRANS Compendium, with the expectation that reported sound levels would closely approximate sound levels for similar piles, driven in a similar manner for this action. Based on the Compendium, impact driving steel sheet piles would be the louder of the two piling types. Back-calculations from measured levels of 189 dB at 10 m and 194 dB at 5 m suggest a SL of 204 dB for sheet piles (Table 2). Back-calculation from a measured level of 173 dB at 10 m suggests a SL of 188 dB for impact driving 16-inch concrete piles, which is the piling described in the compendium that most closely approximates the proposed 16.5-inch concrete piles.

Table 2. Estimated source levels and ranges to effects threshold isopleths for proposed pile driving.

Piling	SL	Range to 180 dB	Range to 160 dB
Steel Sheet	204 dB	40 m	850 m
16-in Concrete	188 dB	3.5 m	74 m

5.2.1.2 Estimate the ranges where in-water sound energy would fall to current threshold for expected effects:

The effects on marine life from exposure to high intensity noises vary with the frequency, intensity, and duration of the sound source, and the hearing characteristics of the exposed animal. Exposure to very high levels of sound can cause soft tissue injuries that could directly result in

fatality. Exposure to lower levels may cause injury in the form of permanent hearing damage, also referred to as permanent threshold shift (PTS). Exposure to even lower levels may cause behavioral effects that include temporary threshold shifts (TTS), temporarily masked communications and/or acoustic environmental cues, and areal avoidance. The cetacean PTS threshold for exposure to in-water sounds is ≥ 180 dB. The same threshold for pinnipeds is ≥ 190 dB. Exposure to impulsive in-water sounds at ≥ 160 dB is the TTS threshold for all marine mammals, whereas the TTS threshold for exposure to non-impulsive sound (continuous noise) is ≥ 120 dB. However, the non-impulsive TTS threshold would not apply because impact pile driving causes impulsive noise.

Green and hawksbill sea turtles are the only ESA-listed marine animals expected to occur within or near Sumay Cove where pile driving noise may reach levels capable of causing adverse effects. As described in Section 3, greens and hawksbills are thought to be low frequency specialists, with hearing ranges that overlap with the expected frequency range of the pile driving signals. Consequently, NMFS expects that green and hawksbills can hear and respond to pile driving noise. Currently, no acoustic thresholds have been established for sea turtles. However, existing research into sea turtle sensory biology suggests that sea turtles are less acoustically sensitive than cetaceans, relying more heavily on visual cues, rather than auditory input (Hazel, *et al*. 2007, Ridgeway *et al*. 1969). The U.S. Navy described recent surveys at Guam where one of its biologists reported green turtles behaving normally on a reef within ~100 m of dredging-related chiseling of a fossilized reef (USN 2011). Although no sound levels were recorded, the biologist reported that he could feel his body physically vibrate due to the concussion of the chisel drop. Despite this, the turtles appeared undisturbed by the activity. This anecdotal evidence supports the idea that sea turtles may be relatively unresponsive to some acoustic stimuli, particularly when compared to marine mammals. Thus, NMFS considers application of the marine mammal thresholds conservative for sea turtles.

Estimating attenuation based on RL = SL - 15logR suggests that the 180 and 160 dB isopleths would occur at ranges of 40 and 850 meters, respectively for the sheet piles, and at 3.5 and 74 meters for the concrete piles (Table 2, and Figure 4). The mouth of Apra Harbor is about 3,700 m from the proposed sheet pile driving, where the estimated received sound level would be about 150 dB.

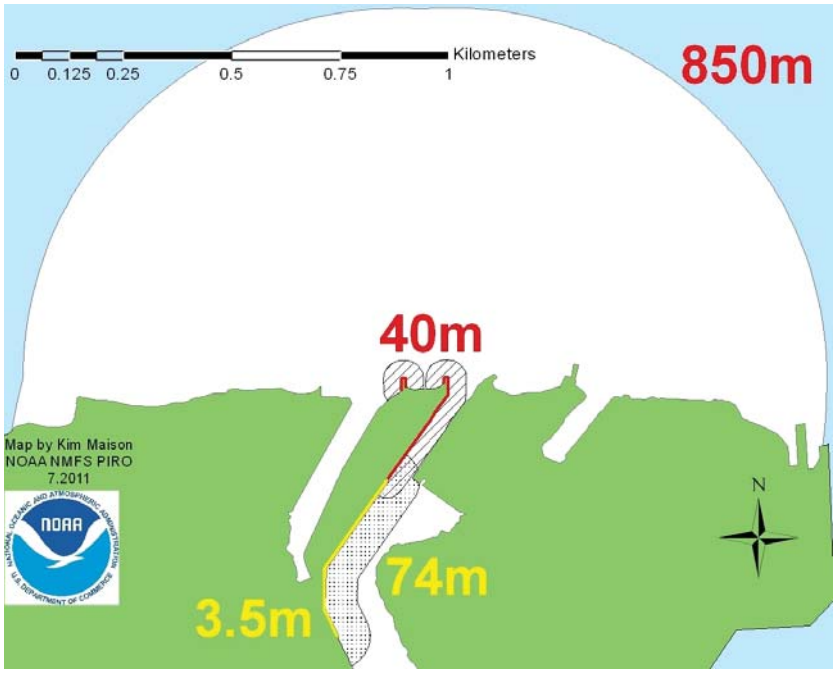

Figure 4. Sumay Cove and Apra Harbor with the 180 dB and 160 dB isopleths indicated (40 m and 850 m for sheet piles; 3.5 m and 74 m for concrete piles).

As mentioned above, transmission loss outside of Apra Harbor is likely to increase because spreading loss is expected increase due the dramatic increase in water depth. Based on the information above, we expect that potentially adverse levels of sound would be restricted to the area within Apra Harbor, and that at most, any ESA-listed animals exposed to pile driving noise outside of the harbor may temporarily experience low levels of masked communications and/or acoustic environmental cues, resulting in insignificant behavioral responses that are likely to range between awareness of the noise to low level areal avoidance.

5.2.1.3. Estimate the number of green or hawksbill sea turtles potentially exposed to adverse levels of sound energy:

Available information suggests that low numbers of green and hawksbill sea turtles reside year-round to rest and forage in nearshore waters around Guam. Sightings confirm ongoing presence of greens in Apra Harbor, including greens periodically observed in Sumay Cove Channel (USN 2011), and low numbers of hawksbills are also expected to occasionally occur in the harbor. However, current data are insufficient to determine precisely the total number or density of either species around Guam or in Apra Harbor. The project BMP require that pile driving be postponed or halted when ESA-listed species are within 46 m (50 yards). As described above, potentially injurious levels of sound, at or above 180 dB, are expected to occur only within 40 m of pile driving, and the Navy has committed to employ acoustic monitoring to verify acoustic propagation and to adjust the shutdown range to ensure that it is protective for turtles. Due to the current inability to quantify the number of turtles likely to be within Apra Harbor, NMFS expects that a low but undeterminable number of turtles within 850 m of the pile driving (range to the 160 dB isopleth) may be exposed to sound levels capable of causing behavioral effects (Figure 4). Based on the expectation that no turtles would be exposed to in-water sound levels approaching the marine mammal threshold for acoustic-related injury, which is considered conservative for sea turtles, NMFS expects that no sea turtles would be exposed to injurious sound levels.

5.3 Response

This section analyzes the responses of green and hawksbill turtles exposed to adverse levels of sound energy during pile driving operations.

5.3.1 Response to Elevated Noise Levels during Pile Driving

The proposed action involves a total of 180 days of daylight work over 30 weeks to impact drive steel sheet piles along 1,000 linear feet of existing seawall. This work is expected to cause potentially adverse levels of in-water sound that may radiate outward to about 850 m. Data regarding the potential response of sea turtles exposed to pile driving noise is are limited, but responses are expected to be context-specific and highly variable. For instance, an exposed turtle in close proximity may become startled by onset of the activity. At greater distances, a reaction that would be best described as awareness is likely. Other reactions to elevated noise could include increased swimming speed, increased surfacing, and movement away from the source. Lenhardt (2002) reported that adult loggerheads initially increase swimming speed and avoided impulsive sounds generated by air guns when received levels ranged from 151 to 175 dB but they eventually habituated to the sound. Moein, *et al.* (1995) reported that upon first exposure, juvenile loggerhead turtles avoided a source that emitted in-water signals at 175, 177, and 179 dB, but the turtles appeared to habituate to the stimuli. However, distances at which the levels

were recorded were not disclosed, and the turtles were enclosed in a net pen. As described above at 5.2.1.2, green turtles were observed near reef chiseling, where the observer reported that his body physically vibrated due to the concussion of the chisel drop. Despite this, the turtles were apparently undisturbed by the activity (USN 2011).

Based on the available evidence NMFS expects that sea turtles in the immediate area near pile driving may initially startle and swim away from the area (behavioral modification) if received levels exceed their tolerance thresholds, which are presently unknown. NMFS is unaware of specific information that would support an estimate of the lateral movement that would be expected for sea turtles under these circumstances. However, NMFS expects that the movement would have no adverse impact on the quantity or quality of available shelter or forage habitat. After initially moving away, some exposed turtles may move back toward the area as they become habituated to the new stimulus, with no measurable impacts expected to occur on those turtles' ability to forage, shelter, and avoid predators or other threats such as vessels.

Based on the information above, NMFS expects that no sea turtles would be injured by exposure to pile driving sounds, and that no behavioral responses are expected to rise to a level that could be considered harassment. Normal behaviors and areal access are expected to return soon after the cessation of pile driving.

5.4 Risk

This section analyzes the risk posed by the proposed action for green and hawksbill turtles exposed to adverse levels of sound energy during pile driving operations.

5.4.1 Risk from Elevated Noise Levels during Pile Driving

Based on the available data used in the exposure and response analyses above, we expect that no green or hawksbill turtles would be injured or killed by this stressor. However, a low but indeterminable number of turtles may be affected through behavioral modification in the form of temporary areal avoidance that would have no measurable impacts on the turtles' ability to forage, shelter, and avoid predators or other threats. As described above in the Status of Listed Species section, resident turtles around Guam likely belong to multiple NAs located elsewhere in Oceania, whereas turtles nesting on Guam likely forage elsewhere, but available genetic information is inadequate to determine which NAs the resident turtles belong to. Although we do not know the exact number of animals that would be affected, we know that the number would be extremely small in comparison to the number of individuals of the affected species found across Oceania, and even larger numbers represented around the world. Given the low number of turtles expected to be affected, that those animals would most likely be from multiple NAs, and the expectation that no injury or reduction in fitness would result due to the proposed action, the risk to the affected nesting aggregations is considered negligible.

5.5 Cumulative Impacts

"Cumulative Impacts" are the additive, synergistic, multiplicative, and/or antagonistic effects that may result from interactions between and among the stressors produced by an action and other pre-existing stressors. As discussed in the environmental baseline section, turtles within Apra Harbor and adjacent marine habitats are routinely exposed to numerous environmental stressors that include shoreline development, poor water quality, frequent close proximity with

human activities in an area where such interactions may result in intentional take, vessel collisions, fisheries interactions, exposure to marine debris, and climate change.

The proposed action is expected to temporarily increase in-water noise levels within Apra Harbor, which would also spread outward somewhat into the Pacific Ocean. Exposure to the proposed action's pile driving noise may result in a short term low-level increase in the stresses experienced by these animals, but that additional stress is expected to be minimal, and to return to background levels shortly (within hours) after the work stops. Based on the best information available, the cumulative impacts of the proposed action are not expected to result in any impacts on ESA-listed marine species not already addressed in the Effects of the Action Section above.

6 Cumulative Effects

"Cumulative effects," as defined in the ESA implementing regulations, are limited to the effects of future State, tribal, local, or private actions that are reasonably certain to occur in the action area considered in this Opinion (50 CFR 402.02). Cumulative effects, as defined in the ESA, do not include the continuation of actions described under the Environmental Baseline, and future Federal actions that are unrelated to the proposed action are not considered in this section because they require separate consultation pursuant to Section 7 of the ESA.

Sources of cumulative effects (coastal development, fisheries interactions, vessel strikes, direct take, marine debris, and climate change) are described in the Environmental Baseline section, and are not only expected to continue, but are likely intensify over time, causing cumulative effects on green and hawksbill sea turtles. The continued growth of the human population on Guam, as well as across the rest of the Pacific region, would likely result in increased coastal development, fishing pressure, vessel traffic, and pollution of the marine environment. Impacts may include accelerated degradation or loss of forage, resting, and nesting habitats; increased take in fisheries including intentional harvest of turtles and eggs; increased vessel strikes; and increased entanglement in, and ingestion of, marine debris. Although the extent of these increased stressors is unquantifiable, and the corresponding effects are also unquantifiable, it is clear that unless adequately addressed to reduce their impacts, these vectors of cumulative effect will present increasing challenges to the continued survival of green and hawksbill sea turtles.

Global climate change is expected to continue and will therefore continue to impact sea turtles and their habitats. Rising temperatures at nesting beaches may continue to exacerbate a female bias and could also increase embryonic mortality if beaches are already at the high end of thermal tolerance for sea turtle nests (Matsuzawa *et al*. 2002). The turtles that occur in the action area likely originate from several NAs, including those that nest on Tutuila, and others that nest on distant islands and atolls. Many of these NAs may be affected by impacts on their nesting beaches of origin throughout the Pacific. The best available demonstrations of the potential effects of sea level rise indicate that some sea turtle nesting beaches will lose a percentage of their current area by 2100 (Fish *et al.* 2005; Baker *et al.* 2006; Fuentes 2009). However, these were modeled on static systems and did not account for geomorphological dynamics. A quantitative analysis of physical changes in 27 atoll islands in the central Pacific over a 19- to 61-year period, that corresponds with a rate of sea level rise of 2.0 mm per year, shows that 86% of islands remained stable (43%) or increased in area (43%) while only 14% of study islands

exhibited a net reduction in island area (Webb & Kench 2010), evidence that changes will not be uniform or predictable and sea level rise may or may not result in beach loss.

Alterations to foraging habitats and prey resources, changes in phenology and reproductive capacity that correlate with fluctuations in SST, and potential changes in migratory pathways and range expansion (all discussed previously in Environmental Baseline) are additional ways in which sea turtles may continue to be impacted by climate change. Many marine species, including the pelagic life stages of sea turtles in the action area, forage in areas of nutrient rich oceanic upwelling, the strength, location, and predictability of which may change with increasing global temperatures (Harwood 2001).

Although there is much speculation on the potential impacts of climate change on species and ecosystems, there are multiple layers of uncertainty associated with these analyses making it impossible to accurately predict the most likely scenario that will result and consequently what impacts species and ecosystems will face, particularly in Pacific Island countries (Barnett 2001). Effects of climate change will not be globally uniform (Walther *et al.* 2002) and information regarding the magnitude of future climate change is speculative and fraught with uncertainties (Nicholls and Mimura 1988). In particular, there is no comprehensive assessment of the potential impacts of climate change within the action area or specific to sea turtles that may be within the action area.

In addition to the uncertainty of the rate, magnitude, and distribution of future climate change and its associated impacts on temporal and spatial scales, the adaptability of species and ecosystems are also unknown. Impact assessment models that include adaptation often base assumptions (about when, how, and to what conditions adaptations might occur) on theoretical principles, inference from observed observations, and arbitrary selection, speculation, or hypothesis (see review in Smit *et al.* 2000). Impacts of climate change and hence its 'seriousness' can be modified by adaptations of various kinds (Tol *et al.* 1998). Ecological systems evolve in an ongoing fashion in response to stimuli of all kinds, including climatic stimuli (Smit *et al.* 2000). Sea turtles may exhibit a variety of adaptations to cope with climate change impacts although it will likely take decades to centuries for these shifts to occur (Limpus 2006) making it increasingly difficult to predict future impacts of climate change on sea turtles in the action area. For example, sea turtles are known to be highly mobile and in the past have shown the ability to adapt to changes in their environment and relocate to more suitable foraging and nesting sites over the course of multiple generations. Implications of climate change at the population level is a key area of uncertainty and one of active research (e.g. Jonzén *et al.* 2007) and currently cannot be reliably quantified in terms of actual mortalities resulting from climate change impacts over any time scale. Nor can they be qualitatively described or predicted in such a way that could be more meaningfully evaluated in the context of this biological opinion. Within the temporal scale of the proposed action, any future synergistic impacts of climate change in the action area that might interact with the effects of the proposed action are not considered significant.

7 Integration and Synthesis of Effects

The purpose of this Opinion is to determine if the proposed action is likely to jeopardize the continued existence of listed species (50 CFR 402.02). "Jeopardize the continued existence of"

means to engage in an action that reasonably would be expected, directly or indirectly, to reduce appreciably the likelihood of both the survival and recovery of a listed species in the wild by reducing the reproduction, numbers, or distribution of that species. This opinion considers the Effects of the Action within the context of the Status of Listed Species and Environmental Baseline, as described in the Approach section (beginning of Section 5 Effects of the Action).

We determine if reduction in fitness to individuals of listed species resulting from the proposed action are sufficient to reduce the viability of the populations those individuals represent (measured using changes in the populations' abundance, reproduction, spatial structure and connectivity, growth rates, or variance in these measures to make inferences about the population's extinction risks). In order to make that determination, we use the population's base condition (established in the Status of Listed Species and Environmental Baseline sections of this opinion), considered together with Cumulative Effects, as the context for the overall effects of the action on the affected populations. Finally, our Opinion determines if changes in population viability are likely to be sufficient to reduce the viability of the species those populations comprise or impair long term recovery of those species, consistent with recovery objectives, as set forth in the species' recovery plan and other sources. The following discussion summarizes the probable risks the proposed action poses to green and hawksbill sea turtles.

7.1 Green Sea Turtles

As described in the Effects of the Action section, we expect that a low but indeterminable number of green turtles could experience behavioral modification in the form of temporary areal avoidance due to exposure to elevated noise levels during pile driving. However, no fatality, injury, harassment, or reduction in fitness is expected to result from this exposure.

As discussed in the Status of Listed Species, about 18,000 to 38,000 green turtles nest annually in Oceania (adult females only). Although a low number of green turtles reside in the nearshore waters around Tutuila (sub-adults and adults of both sexes), that number is currently unknown, and no population trend data are available. As summarized in Figure 2, many of the major green sea turtle nesting aggregations in Oceania are stable or increasing, while many of the smaller nesting aggregations are declining. As discussed more fully in the Environmental Baseline and Cumulative Effects sections, the effects of coastal development, fisheries interactions, vessel strikes, direct take, marine debris, and climate change within the action area are expected to continue, and likely worsen, in the future. However, the impact and time scale of these effects on the trajectory of the affected green turtle populations is currently uncertain, and those impacts are expected to occur on a time scale, against which the impacts of the proposed action would be indistinguishable.

Because the proposed action is anticipated to result in no fatality, injury, harassment, or reduction in fitness of green turtles around Guam, the impacts of the proposed action are not expected to reduce the reproduction or abundance of green turtles there, or to impede the recovery of that species around the island. As described in the Status of Listed Species, the turtles found in Guam's waters represent a very small proportion of green turtles across Oceania. They originate from multiple NAs, and the largest NAs in Oceania are increasing. Given that the proposed action is expected to result in no injury or reduction in fitness or reproduction of green turtles at the level of the individual, we expect that the impacts of the proposed action would not

reduce the reproduction, abundance, or distribution, or recovery of the affected green sea turtle NAs. As such, the proposed action is not expected to negatively affect the survival or recovery of green sea turtles in Oceania. Therefore, when taken in context with the status of the species, the environmental baseline, cumulative impacts and effects, the proposed action is not likely to appreciably reduce the likelihood of survival and recovery of this species, as listed under the ESA.

7.2 Hawksbill Sea Turtles

As described in the Effects of the Action section, we expect that a low but indeterminable number of hawksbill turtles could experience behavioral modification in the form of temporary areal avoidance due to exposure to elevated noise levels during pile driving. However, no fatality, injury, harassment, or reduction in fitness is expected to result from this exposure.

As discussed in the Status of Listed Species, about 5,400 to 6,100 hawksbill turtles nest annually in Oceania (adult females only). Although a low number of hawksbill turtles reside in the nearshore waters around Tutuila (sub-adults and adults of both sexes), that number is currently unknown, and no population trend data are available. As discussed in the Status of Listed Species, hawksbill sea turtle nesting aggregations in Oceania are generally decreasing. As discussed more fully in the Environmental Baseline and Cumulative Effects sections, the effects of coastal development, fisheries interactions, vessel strikes, direct take, marine debris, and climate change within the action area are expected to continue, and likely worsen in the future. However, the impact and time scale of these effects on the trajectory of the affected hawksbill turtle populations is currently uncertain, and those impacts are expected to occur on a time scale, against which the impacts of the proposed action would be indistinguishable.

Because the proposed action is anticipated to result in no fatality, injury, harassment, or reduction in fitness of hawksbill turtles around Guam, the impacts of the proposed action are not expected to reduce the reproduction or abundance of hawksbill turtles there, or to impede the recovery of that species around the island. As described in the status of the Status of Listed Species, the hawksbill turtles found in Guam's waters represent a very small proportion of hawksbill turtles across Oceania. They originate from multiple NAs, the number and locations of which are currently unknown, but the population trends at those NAs could be decreasing. Given that the proposed action is expected to result in no injury or reduction in fitness or reproduction of hawksbill turtles at the level of the individual, we expect that the impacts of the proposed action would not reduce the reproduction, abundance, or distribution, or recovery of the affected hawksbill turtle NAs. As such, the proposed action is not expected to negatively affect the survival or recovery of hawksbill turtles in Oceania. Therefore, when taken in context with the status of the species, the environmental baseline, cumulative impacts and effects, the proposed action is not likely to appreciably reduce the likelihood of survival and recovery of this species, as listed under the ESA.

8 Conclusion

After reviewing the current status of ESA-listed green and hawksbill sea turtles, the environmental baseline for the action area, the effects of the proposed action, and the cumulative effects, it is NMFS' Opinion that the Navy's proposed Sumay Cove Repair and Modernization in Apra Harbor, Guam is not likely to jeopardize the continued existence of green sea turtles or hawksbill sea turtles.

As described above in Section 3, no critical habitat has been designated or proposed for designation for any ESA-listed marine species in the action area or elsewhere in the Mariana Archipelago. Therefore, the proposed action would have no effect on designated or proposed critical habitat under NMFS jurisdiction.

9 Incidental Take Statement

Section 9 of the ESA and protective regulations pursuant to Section 4(d) of the ESA prohibit the take of endangered and threatened species without a special exemption. "Take" is defined as to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, collect, or attempt to engage in any such conduct. "Incidental take" is defined as take that is incidental to, and not the purpose of, the carrying out of an otherwise lawful activity. Under the terms of Section 7(b)(4) and section 7(o)(2), taking that is incidental to and not intended as part of the agency action is not considered to be prohibited taking under the ESA provided that such taking is in compliance with the reasonable and prudent measures and terms and conditions of the Incidental Take Statement (ITS).

Based on the best information available, implementation of the proposed action is expected to adversely affect an indeterminable number of green and hawksbill sea turtles over a period of 30 weeks, through some level of areal avoidance. Although NMFS has determined that these impacts constitute adverse effects for green and hawksbill sea turtles, we have also determined that the expected effects would not rise to the level of take because the turtles' expected response to the stressors are expected to cause no measurable harm to or harassment of those animals. Because no take is expected, no ITS is necessary, nor can an ITS be issued for this action.

10 Conservation Recommendations

Section 7(a)(1) of the ESA directs Federal agencies to utilize their authorities to further the purposes of the ESA by carrying out conservation programs for the benefit of endangered and threatened species. Conservation recommendations are discretionary agency activities to minimize or avoid adverse effects of a proposed action on listed species or critical habitat, to help implement recovery plans, or develop information.

The following conservation recommendations are provided pursuant to Section 7(a)(1) of the ESA:

1. The Navy is strongly encouraged to use acoustic attenuation devices, such as bubble curtains, to reduce the acoustic impacts of pile driving on ESA-listed species in their marine habitats.
2. The Navy is strongly encouraged to perform comprehensive debris and trash removal at the project site and nearby areas, beyond that of construction-related materials to improve turtle habitats (i.e. Spanish Steps Beach).
3. The Navy is strongly encouraged to use outreach, such as signage and educational programs, to improve the awareness of military personnel on Guam of the status of sea turtles, including their vulnerability vessel collision and habitat loss, and measures that can be taken to reduce impacts.

11 Reinitiation Notice

This concludes formal consultation on the U.S. Navy' proposed Sumay Cove Repair and Modernization, Naval Base Guam. As provided in 50 CFR 402.16, reinitiation of formal consultation is required where discretionary Federal agency involvement or control over the action has been retained or is authorized by law, and if:

1. The amount or extent of anticipated incidental take is exceeded;
2. New information reveals effects of the agency action that may affect listed species or critical habitat in a manner or to an extent not considered in this Opinion;
3. The agency action is subsequently modified in a manner that may affect listed species or critical habitat to an extent, or in a manner not considered in this Opinion; or
4. A new species is listed or critical habitat designated that may be affected by the action.

Mr. John F. Salas, Professional Engineer
Department of the Navy
Naval Facilities Engineering Command, Marianas
PSC 455, Box 195
FPO AP 96540-2937

Subject: Biological Opinion for Brown Tree Snake Control in the Habitat Management Unit, Andersen Air Force Base, Guam

Dear Mr. Salas:

This letter transmits the U.S. Fish and Wildlife Service's (Service) Biological Opinion on the Department of the Navy's (DON) proposed brown tree snake (*Boiga irregularis*) (brown treesnake, BTS) control in the Habitat Management Unit (HMU), Andersen Air Force Base, Guam on the threatened Mariana fruit bat (Fanihi, *Pteropus mariannus mariannus*). Formal consultation on the proposed action was conducted in accordance with section 7 of the Endangered Species Act of 1973 [16 U.S.C. 1531-1544 *et seq*.], as amended (Act). Your request for formal consultation and Biological Assessment were received on December 15, 2017.

Your December 15, 2017, letter and Biological Assessment included a request for Service concurrence with the DON's determination the proposed action may affect but is not likely to adversely affect four threatened plant species (Fadang (*Cycas micronesica*), *Tabernaemontana rotensis*, Cebello halumtano (Siboyas halumtano, *Bulbophyllum guamense*), and *Tuberolabium guamense*)) and three endangered tree snails (Fragile tree snail (*Samoana fragilis*), Guam tree snail (*Partula radiolata*), and Humped tree snail (*Partula gibba*) (tree snails). Our concurrence with the DON's not likely to adversely affect determinations for the four threatened plant species and three endangered tree snail species in addition to the rationale for these concurrences is located in **Appendix A**.

The enclosed Biological Opinion is based on information provided in the December 2017, Biological Assessment and information provided by DON Natural Resource staff, and telephone conversations, field investigations, and other sources of information cited in this Biological Opinion. A complete record of this consultation is on file at the Pacific Islands Fish and Wildlife Office.

CONSULTATION HISTORY

The following is a summary of important events associated with this consultation:

September 1, 2017: Department of the Navy (DON) personnel (Jim Watkins, M. J. Mazurek, and Paula Hartzell) met with the USFWS biologists (Catherine Brunson and Toni Mizerek) in Hagatna, Guam to discuss the Proposed Action, Action Area, actions that may affect listed species, best management practices, and the timeline for formal consultation.

September 25, 28, and 02, October 2017: Emails were exchanged among the USFWS and DON, on the potential for listed tree snails to be present in the Proposed Action Area and conservation measures to avoid tree snails, if present.

December 15, 2017: The Service received your letter requesting initiation of formal section 7 consultation pursuant to the Act and the project's December 2017 Biological Assessment. The Biological Assessment indicated the proposed action was likely to adversely affect all Mariana fruit bats within and immediately adjacent to the HMU in the form of: (1) harassment as a result of low-level helicopter flights used to apply BTS baits, (2) harassment in the from biological ground-monitoring activities, or (3) death or injury associated with potential helicopter strike. The Biological Assessment concluded the proposed action was not likely to adversely affect the Guam tree snail, the humped tree snail, the fragile tree snail, *Cycas micronesica*, *Bulbophyllum guamense*, *Tabernaemontana rotensis*, or *Tuberolabium guamense*.

December 29, 2017: Department of the Navy Natural Resource Specialist M.J. Mazurek confirmed via telephone the Department of Defense's plans to control rodents in the project site to ensure the suppression of brown treesnake population does not result in increased predation of listed tree snails and plants should an increase in rodent population occur as a result of suppression of the BTS or as part of implementation of the Andersen Air Force Base, Habitat Management Unit Restoration Plan (Siers and Savidge 2017).

January 10, 2018: The Service confirmed formal consultation was initiated on December 15, 2017.

January 19 – February 14, 2018: Service biologists Dawn Bruns and Toni Mizerek and DON Natural Resource Specialist M.J. Mazurek coordinated with endangered plant and tree snail specialists to refine the following project conservation measures: general biosecurity measures, endangered plant offset distances, and refined bait drop timing measures to minimize the potential for tree snails to be dislodged from trees by bait drop operations.

February 21, 2018: Service biologist Dawn Bruns provided DON Natural Resource Specialist M.J. Mazurek with a draft assessment of the potential for bait drops to dislodge tree snails and for tree snails on the ground to be inadvertently crushed by personnel implementing the proposed BTS and rodent control actions.

March 13, April 5, and April 11, 2018: Department of the Navy Natural Resource Specialist, M.J. Mazurek, and Senior Natural Resources Specialist, Coralie Cobb, and the USFWS

biologists, Dawn Bruns and Toni Mizerek, discussed modifications to the project duration to minimize the potential for adverse effects to tree snails.

April 11, 2018: Department of the Navy Natural Resource Specialist, M.J. Mazurek, and Senior Natural Resources Specialist, Coralie Cobb, agreed to reduce the amount of field staff off-trail walking from the 536 "events" (an "event" is two people traversing 26 trackless transects approximately 656.2 ft in length) which would entail and estimated 1,575 miles of off-trail walking proposed in the Biological Assessment, to 406 "events" (approximately 1,195 miles of off-trail walking) to minimize the potential for field staff to trample a tree snail were integrated into the project.

April 19, 2018: Department of the Navy Natural Resource Specialist, M.J. Mazurek, and Senior Natural Resources Specialist, Coralie Cobb, confirmed by phone the proposed action would be put on hold during any period when a rodent control response was not available.

April 23, 2018: Department of the Navy Natural Resource Specialist, M.J. Mazurek transmitted the text of the project description of this Biological Opinion to the Service.

April 29, 2018: Department of the Navy Natural Resource Specialist, M.J. Mazurek confirmed the Service's request for an extension to the completion date of the Biological Opinion to May 22, 2018 to accommodate the interagency effort that had been undertaken to compile new information about tree snail abundance and distribution to inform the analysis of project effects.

May 5, 2018: The Service provided the Department of the Navy with a Draft Biological Opinion.

May 10, 2018: The Department of the Navy transmitted the Draft Biological Opinion back to the Service.

BIOLOGICAL OPINION

Proposed Action

The BTS is a non-native invasive species that has caused the steep decline of native vertebrates on Guam. Development and implementation of landscape-scale suppression methods is necessary for recovery of listed Guam vertebrates and to minimize the likelihood the snake will be inadvertently moved from Guam to other locations. The proposed action is a high priority of the interagency Brown Treesnake Technical Working Group, the Service, the Department of Defense, and partner agencies, because it further develops landscape-scale BTS suppression methods and it further reduces snake numbers to enable the HMU to provide habitat for the Mariana fruit bat, Mariana crow (*Corvus kubaryi*), and Guam Micronesian kingfisher (*Todiramphus* [=*Halcyon*] *cinnamominus cinnamominus*), Guam rail (*Gallirallus owstoni*), and other federally-listed species. Information obtained during project implementation will guide design of long-term landscape-scale BTS and rodent detection, monitoring, and control rodent control actions within the HMU and elsewhere on Guam.

The Proposed Action entails the aerial application of acetaminophen for BTS suppression in the HMU, Andersen Air Force Base (AAFB), Guam and associated ground-based field work. The HMU is a 135 ac interagency test site established for biological resource studies, including pilot control and monitoring programs for invasive species and forest restoration. BTS bait containing acetaminophen will be delivered over the HMU via the helicopter-mounted automated aerial delivery system. Ground-based BTS and rodent monitoring will occur up to two months prior to the aerial bait application operations. In addition, ground crews will monitor and implement ground-based BTS and rodent monitoring during aerial bait applications and for approximately one year following aerial BTS baiting operations. Loaded bait cartridges weigh approximately 0.5 oz and they will be dropped during daylight periods, between 0900 and 1800 hours. The automated bait dispensing module delivers baits at a rate of up to four per second. The allowable labeled rate is 50 baits/ac per application, with a minimum interval of three days between drops, no more than 150 baits per acre within a four-month period, and no more than 450 baits per acre within a single year (USEPA Registration # 56228-34, EPA Est. No. 56228-CO-01, "Acetaminophen for brown treesnake control"). BTS and rodent ground-based monitoring would occur during various daylight hours and BTS visual surveys would be conducted between 1800 (6:00 PM) and midnight.

Aerial bait applications will be conducted using a rotary-winged aircraft similar to a Hughes MD 500, or similar, helicopter. Calibration bait drops will be conducted to calibrate bait deployment procedures and equipment along the road bounding the northeast edge of the HMU (shown in yellow on Figure 4). The calibration bait equipment is identical to that used in the HMU. The calibration baits will not be recovered. Bait will consist of an acetaminophen tablet attached to a dead neonatal mouse. Bait cartridges (Figure 1) are automatically dispensed at the prescribed application rate using the automated delivery system dispensing system module. Helicopter flights dispensing bait would be made flying along georeferenced transects loaded in the onboard helicopter navigation system. Flights would occur at approximately 82 to 328 ft above the forest canopy in the HMU at an average flight speed of 50 to 70 knots. Flight transects are separated by 29.5 ft. A single application of bait to the entirety of the HMU at the above described application rate would take approximately two hours of helicopter flight time to complete.

Bait cartridges consist of a dead neonatal mouse (DNM) weighing 0.17 to 0.25 oz, with a 0.0028 oz acetaminophen tablet glued to the exterior surface of the DNM. The DNM/acetaminophen tablet is glued to the interior surface of a pulp paper 'clamshell' which closes over the mouse. A biodegradable ribbon is wrapped around and glued to the clamshell and a pulp paper endcap. The bait/clamshell/ ribbon/endcap assemblage is inserted into the cardboard tube for a completed bait cartridge (see Figure 1). A complete bait cartridge weight is approximately 0.55 ounces. The bait cartridge is ejected from the dispensing system module (DSM) such that it spins; the inertia of the bait cartridge assembly causes the clamshell to slide out of the spinning tube, deploying the ribbon as the bait assembly falls through the air. The ribbon then becomes entangled in the forest canopy, thus causing the assembly to be suspended above the ground (see Figure 1). All components of the cartridge assembly are biodegradable. The ribbon and bait cartridges should degrade within a day during heavy rains but could persist for a week or more during dry seasons. The bait generally degrades within 3 to 4 days of application.

Figure 1. Depiction of the deployed bait cartridge entangled in vegetation (photo credit: M.J. Mazurek).

Monitoring

Aerial bait application efficacy will be evaluated on the day of and/or first day following aerial bait applications. Two observers will traverse the HMU on 20 trackless transects (see below), approximately 1,575 ft in length and record the number of opened and unopened cartridges and height above ground relative to the canopy. The Proposed Action includes pre- and post-drop ground-based monitoring of BTS and their prey using a variety of established survey methods. Ground-based monitoring would occur up to two months prior to the first bait application and for up to one year following each bait drop. BTS would be monitored using visual surveys, bait tube monitoring, and radio-telemetry of snakes. Non-target species would be monitored using several non-invasive methods.

Two types of survey approaches would be utilized for ground-based surveys within the HMU, including fixed maintained transects and randomly placed trackless transects. The fixed transect survey method would require maintaining passable marked monitoring transects with limited pruning of vegetation using non-powered hand tools. Maintained transects will be no greater than 3.3 ft in width. Transect lengths would vary dependent on survey method.

Trackless surveys begin at a randomly chosen location and proceed for a pre-determined distance (depending on survey method) along a randomly-chosen compass bearing. Trackless surveys do not require the creation and maintenance of pruned and marked transects. Trackless transects

reduce permanent damage to vegetation at discrete locations since survey routes are not maintained. Field personnel engaged in monitoring activities on trackless transects would be instructed to move carefully and purposefully through the vegetation, avoiding contact with listed plant species and maintaining an awareness for listed tree snails and butterfly host plants.

BTS bait tube monitoring would occur along trackless transects with randomly located starting points. Ten bait tubes (Figure 2) would be placed every 65.6 ft for a total of 656 ft along a random compass bearing. Four to ten temporary transects would be set and baited weekly; two days later they would be checked and the baits removed.

Visual surveys for BTS are conducted by pairs of trained observers walking at a consistent rate, and visually scanning vegetation for snakes using high-powered headlamps. Surveys are conducted after sunset and last typically four to five hours. Once snakes are located they are hand-captured, morphometric data is collected, and snakes are marked and released at the location of capture. Visual surveys would be conducted using both trackless and maintained transects survey methodology:

- 26 fixed maintained transects at approximately 262.5 ft spacing, dependent upon avoidance of listed species if present, each 656.2 ft in length. Maintained transects would be no greater than 3.3 ft in width.
- 26 trackless transects at 262.5 ft intervals and 656.2 ft in length; placement dependent on location of maintained transects. Observers would walk parallel and not in single file formation.

Traps and visual surveys would be used to capture 50 to 60 BTS within the HMU to be radio-marked. Traps would ideally be placed along maintained transects and the forest edges. If maintained transects are unavailable then traps would be placed along trackless transects and marked with flagging tape. Traps would not be affixed to listed species and all material and flagging would be removed after trapping surveys are completed. Radio-transmitters would be externally attached to the snakes. Those snakes would be returned to the site prior to the application of the bait.

Telemetry monitoring consists of survey personnel traversing the HMU to locate telemetered-snakes. Telemetered snakes would be monitored every other day, for 4 to 6 weeks prior to the first aerial bait application. Following bait applications, snakes would be monitored daily for two weeks to determine the proportion of known snakes that were effectively targeted by the treatment. Dead telemetered snakes would be necropsied and those that survive would be followed to determine movement activity and microhabitat selection. Surviving snakes would be located every other day for an additional 4 to 6 weeks to evaluate behavioral changes following BTS population suppression. At the close of the study, any remaining telemetered snakes would be removed and euthanized.

Figure 2. Brown tree snake PVC bait tubes with cameras mounted to view the bait tubes (Photo credit: USDA NWRC).

Rodents would be monitored to assess changes in abundance from snake suppression. Rodent abundance would be monitored using a combination of mark-recapture trapping, track tunnels, and chew tags. Track tunnels and chew tag methods have been widely used to assess island rodent eradication efforts and eradication efforts within predator-fenced areas (Sweetapple and Nugent 2011; Reardon et al. 2012; Young et al. 2013). Eleven trackless transects would form a trapping grid of 121 traps. Traps and track tunnels would be placed on the ground and chew tags would be suspended in vegetation. Ground disturbance associated with rodent monitoring methods would include only placement of live-traps, which would be removed immediately upon the close of the sampling event. Rodent stations would occur on a monitoring grid of 11 trackless transects, at 41 ft intervals of 451.1 ft in length. Four replicated grids would be placed within the HMU for rodent monitoring.

Conservation Measures

The proposed action has the potential to directly and indirectly result in adverse effects to listed plants and animals. To minimize these potential effects, the conservation measures outlined in the Biological Assessment, in addition to conservation measures drafted during the formal consultation coordination, are incorporated into the project design.

Conservation measures in the Biological Assessment: The conservation measures in Table 1 will be implemented to minimize adverse effects to non-target species.

Locations of federally-listed plant species within the HMU have been determined based on systematic surveys conducted in 2015 (GPEPP 2015). Listed plant locations were recorded and input into a geographic information systems (GIS) data base. BTS monitoring teams would use GPS units with listed plant species location data to avoid locations occupied by listed plants.

While there are currently no known records of listed snails in the Action Area, survey data are incomplete and potential exists that the habitat may be suitable for some of these species. The risk minimization measures specified below would lessen impacts to these species if they do exist undiscovered in the Action Area (USDA NWRC 2017).

Table 1. Conservation measures included in the Biological Assessment.

Conservation Measures	Description	Impacts Reduced/Avoided
Mariana Fruit Bat Surveys on Bait Application Days	Fruit bat surveys would be conducted at dawn around the HMU perimeter on the morning of helicopter bait applications. Methods would follow established survey methods for fruit bats (DON 2016).	Establish fruit bat presence in the HMU on the intended date of bait application to inform helicopter crew of potential strike risk to fruit bats.
Helicopter Bait Application Schedule Restrictions*	Helicopter bait applications would occur after 0900 hours.	Fruit bats activity has been observed to decrease after 0900 (Wheeler 1979).
Bio-monitors for Mariana Fruit Bat Bait Application Behavioral Response Documentation*	Fruit bat monitors would be present at the HMU perimeter during helicopter bait applications and document any disturbance and behavioral response of fruit bats (if present) resulting from the bait application.	Information would be compiled to inform future similar actions that may occur in bat occupied sites and document if any incidental take occurs.
Mariana Fruit Bat Ground Monitoring Documentation	If fruit bats are observed within the HMU by biological monitoring teams, the location and number of individuals would be recorded and reported to the DON within 24 hours. Survey personnel would record bat behavior on standardized data forms.	Information would be compiled to inform future similar actions that may occur in bat occupied sites and documented in annual reports to the Service in accordance with an incidental take statement.
Maintained Transects Bio-monitor	Qualified biologist/Bio-monitor* would inspect vegetation that would be pruned in the creation of maintained transects to confirm the plant is not a federally-listed species. Plant matter to be clipped would be inspected for listed tree snail presence and there would be a prohibition against trimming or damaging plants or tree limbs occupied by listed tree snails. Transects would be modified to avoid occupied plants and tree limbs, and field staff would avoid disturbing snails while working along transects in tree snail occupied areas.	Avoid impacts to listed species.
Listed Plant Species Avoidance Protocol	All listed plant species that are ground accessible would be flagged adjacent to the individual with a unique color to denote status as protected. GPS locations would be loaded into biological monitoring team GPS units for additional awareness. No traps, bait tubes, or other monitoring devices would be placed on listed plant species.	Avoid impacts to listed plant species.

*Qualified biologist/Bio-monitor would have experience in the identification of and survey methods for federally listed species.

For maintained transects, the following protocols and conservation measures outlined in the BA would be implemented:

- A qualified biologist/biomonitor would inspect vegetation that would be pruned in the creation of maintained transects to confirm the plant is not a federally-listed species and to confirm the vegetation is not occupied by a listed tree snail. Vegetation needing to be modified by pruning would be flagged. Listed species would not be flagged.
    - If listed species is detected, the transect location would be altered to avoid contact with the individual.
    - Plant matter to be clipped would be inspected for listed tree snail presence and there would be a prohibition against trimming or damaging plants or tree limbs occupied by listed tree snails.
    - Transects would be modified to avoid occupied plants and tree limbs, and field staff would avoid disturbing snails while working along transects in tree snail occupied areas.
- No whole plants would be removed.
- Pruning of vegetation would be minimized to the extent practicable. All green material would remain on site.
- Known listed plants and butterfly host plants in the treatment area would be identified with flagging attached to adjacent non-listed plants to aid field personnel in identification and notification of avoidance.
- Only common plants of known identity and non-protected status would be trimmed.
- No survey gear would be affixed or come into contact with any listed species.
- No use of power tools for pruning vegetation.

Best Management Practices (BMPs) are policies and measures that would be implemented to minimize environmental impacts from the proposed action (Table 2). Best Management Practices are those that may not be unique to this proposed action but also implemented into other project descriptions.

Table 2. Best Management Practices from Biological Assessment.

Best Management Practice	Description
Biologist Federally-listed Species Identification Training Program	All biological monitoring personnel would be required to attend a federally-listed species training program conducted by a qualified professional biologist(s)*. Training would include classroom and field identification training and personnel would be provided species identification cards for use in the field during survey efforts. Standardized recording methods and data forms would be required for use by survey teams if newly listed species are discovered as a result of BTS monitoring efforts.
Notification of Federally- listed Tree Snail Presence	If federally-listed tree snails are discovered by teams conducting scientific biological field studies, the DON would be notified within 24 hours of discovery. Delineation of the distribution of the tree snails would be conducted by qualified biologists and those areas would be avoided.

*Qualified biologist/Bio-monitor would have experience in the identification of and surveys for federally listed species.

Refinements to Conservation Measures Developed After Initiation of Formal Consultation:

General Biosecurity Measures: Standard biosecurity measures will be implemented to minimize the potential for the introduction or movement of non-native invasive weeds and invertebrates. Boots, clothing, field gear (packs, rain gear, etc.), equipment, and materials will be inspected for seeds, eggs, larvae, etc., prior to delivery and/or entry into the project area, and these items will be cleaned prior to entering the HMU. Helicopter landing zones will be monitored for weed species, invasive ants, and other invasive invertebrates that may be dispersed into the HMU on the helicopter landing gear. Helicopter landing sites will be kept free of those weed and invertebrate species that are not already established within the HMU.

Buffer Distances: To minimize the likelihood of trampling or dislodging a tree snail, project staff will not walk within 33 ft of a marked tree snail area (if identified) and no vegetation will be cut or removed within 200 ft of the occupied area.

To minimize potential damage to listed plants when activities may result in soil compaction or vegetation disturbance, the buffer distances in Table 3 will be implemented. In addition, native trees will not be removed during project implementation.

Table 3. Plant buffer distances.

Type of Action: Nature and Extent of Soil or Vegetation Disturbance	**Listed Plants: Buffer Distance: Project Activity Will Not Be Conducted Closer Than Distance Note**		
	Listed Epiphyte	**Listed Herb/Shrub**	**Listed Tree**
Weeding/removing non-native understory vegetation by hand or using non-mechanized hand tools.	0 feet	3 feet	3 feet
Removal of less than 10-foot width and less than five acres (project total) of native understory vegetation with hand tools (weeding, chainsaw, weed eater). No project-related mortality of over story native vegetation. Trails through understory vegetation. Less than three feet width of bare mineral soil.	0 feet	20 feet	2x diameter of the crown of the listed tree

Field Work Following Typhoon: Because tree snails are likely to be dislodged from the vegetation during a typhoon, ground crews will not work within the HMU during a seven day period following a typhoon category 3 or higher recorded on AAFB.

Rodent Control: The Proposed Action does not control for rodents and is designed to study rodent population response to BTS suppression. Continuation of the BTS project will be reliant on rodent control implementation: during any period when the rodent control action becomes unavailable, the proposed BTS control action will be halted.

Action Area

The Action Area is defined as all areas to be affected directly or indirectly by the federal action and not merely the immediate area involved in the action (50 CFR 402.02). In delineating the Action Area, we evaluated the farthest reaching physical, chemical, and biotic effects of the action on the environment. Aerial application of the BTS toxicant will occur on the 135 ac HMU in northern Guam (Figures 1 and 2). The Action Area consists of the proposed treatment area within the HMU, the areas affected by noise and disturbance from helicopter flights between the landing zones and helicopter ground support operations areas (locations to be determined). The landing zone and ground support operations areas may be on AAFB (at the interior of the Detachment-2 gate; off of Route 3A or off Route 1 at Andersen South, in Dededo) or elsewhere in cleared areas in north Guam. The Action Area for this proposed federal action is based on the geographic extent of helicopter noise at the HMU project site and in north Guam areas that may be traversed by project helicopters. Project-related aircraft will transit among north Guam airfields, staging areas, and bait drop sites. Areas used by project helicopters will land at a landing zone in a ground support operations area to the interior of the DET 2 gate (Detachment-2 gate; off of Route 3A) or off Route 1 at Andersen South (AltLZ), AAFB in Dededo.

There is designated critical habitat in the northern portion of Guam at the Ritidian Unit of the Guam National Wildlife Refuge (GNWR), but it is not within the Action Area of this Biological Opinion, as the area would not be directly or indirectly affected by the proposed action.

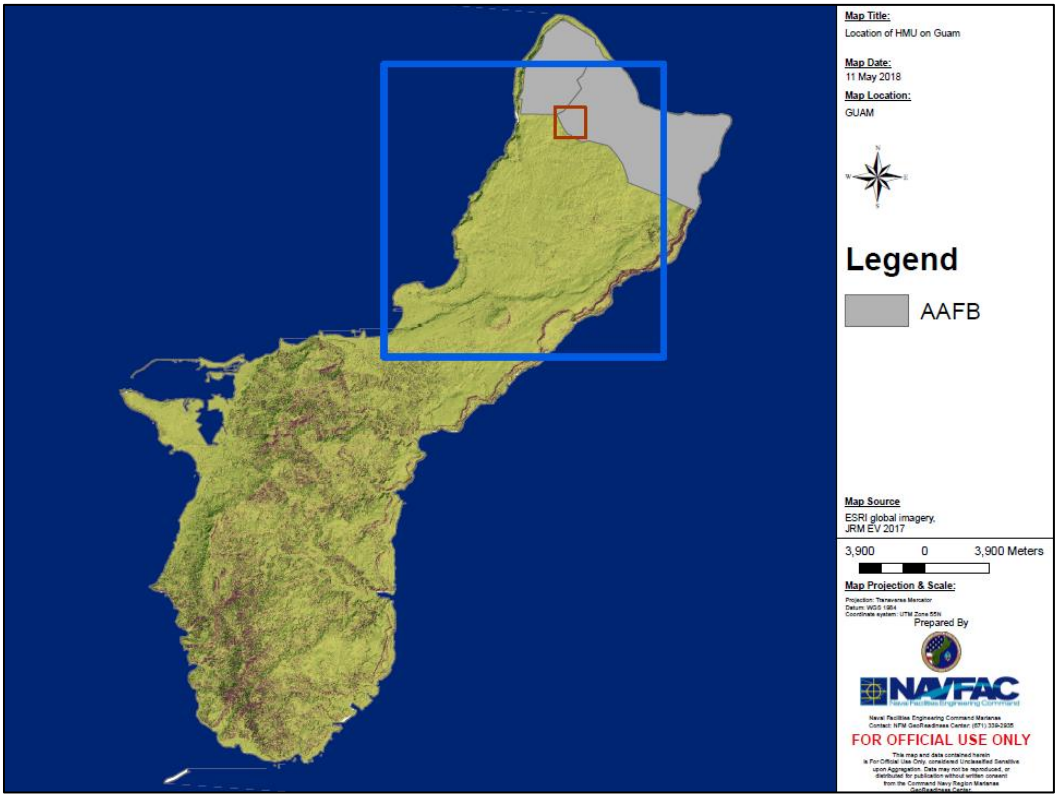

Figure 3. The proposed BTS suppression work will target the HMU (within the red box, see Figure 4) and helicopters working on the proposed BTS bait drop actions may land and overfly additional areas within the blue box.

Figure 4. The HMU conservation area (outlined in red) on Andersen Air Force Base, Guam and the helicopter flight path for calibration of the automated delivery system (shown in yellow dashed line).

ANALYTICAL FRAMEWORK FOR THE JEOPARDY DETERMINATIONS

Jeopardy Determination

The following analysis relies on the following four components: (1) the *Status of the Species*, which evaluates the range-wide condition of the listed species addressed, the factors responsible for that condition, and the species' survival and recovery needs; (2) the *Environmental Baseline*, which evaluates the condition of the species in the action area, the factors responsible for that condition, and the relationship of the Action Area to the survival and recovery of the species; (3) the *Effects of the Action*, which determines the direct and indirect impacts of the proposed Federal action and the effects of any interrelated or interdependent activities on the species; and (4) *Cumulative Effects*, which evaluates the effects of future, non-federal activities in the action area on the species.

In accordance with policy and regulation, the jeopardy determination is made by evaluating the effects of the proposed federal action in the context of the species' current status, taking into account any cumulative effects, to determine if implementation of the proposed paction is likely

to cause an appreciable reduction in the likelihood of both the survival and recovery of listed species in the wild.

The jeopardy analysis in this Biological Opinion emphasizes the range wide survival and recovery needs of the listed species and the role of the action area in providing for those needs. It is within this context that we evaluate the significance of the proposed Federal action, taken together with cumulative effects, for purposes of making the jeopardy determination.

STATUS OF THE SPECIES

Species Description

The Mariana fruit bat was listed as endangered in 1984, but was reclassified to threatened on January 6, 2005, when it was determined that all fruit bats on Guam and throughout the Commonwealth of the Northern Mariana Islands (CNMI) comprise a single subspecies (70 FR 1190). The Mariana fruit bat is the only fruit bat species under U.S. jurisdiction. In 2004, critical habitat for the fruit bat was designated at the GNWR in the Ritidian Unit (69 FR 62944).

The Mariana fruit bat is a medium-sized fruit bat in the family Pteropodidae, and weighs between 0.73 lb to 1.27 lb (331 g to 577 g). Male Mariana fruit bats are slightly larger than females. The underside (abdomen) is black to brown with gray hair interspersed that creates a grizzled appearance. The shoulders (mantle) and sides of the neck are bright golden brown, but may be paler in some individuals. The head varies from brown to dark brown. The well-formed, rounded ears and large eyes give the face a canine appearance (USFWS 2010 p. 4).

The paleotropical genus *Pteropus* is represented by approximately 63 species distributed across the Indian Ocean, Southern Asia, Australia, and in Oceania as far east as the Cook Islands (Almeida et al. 2014 p. 83). Most species in the genus *Pteropus* occur on islands or in coastal areas (Almeida et al. 2014 p. 84). Four species in the genus *Pteropus* are extinct and 38 species (60 percent of the genus) are considered critically endangered, endangered, threatened, near threatened, or vulnerable under the definitions of the IUCN (IUCN 2017). One of the four extinct species, *P. tokudae*, occurred only on Guam and has not been detected since 1968 (Bonaccorso et al. 2008; USFWS 2010).

Flannery (1995) and Simmons (2005) consider the Mariana fruit bat as one of two subspecies of fruit bats restricted to the Mariana Archipelago, with the Mariana fruit bat inhabiting the islands from Guam to Saipan and *P. mariannus paganensis* occurring on Pagan and Alamagan islands. However, subsequent genetic analysis conducted by Brown et al. (2011) indicate no genetic differentiation among islands within the Mariana Archipelago and that the bats on these islands, currently classified as two subspecies, should be managed as a single subspecies, *P. mariannus mariannus* (p. 940). In addition to the Mariana fruit bat, there are several other subspecies of *P. mariannus* endemic to other archipelagos, including the Caroline Islands and the Palau Archipelago (Brown et al. 2011 p. 934).

Life History

Mariana fruit bats, similar to other bats in the Pteropodidae family, do not use laryngeal echolocation, instead relying primarily on vision and smell to avoid obstacles and locate food sources (Almeida et al. 2014). Mariana fruit bats vocalize readily within colonies and when roosting. The diet of the Mariana fruit bat is comprised of fruits, nectar, pollen, and some leaves from at least 45 different plant species (Mildenstein & Johnson 2017). Rapid digestion and metabolism of food makes these animals reliant on forest habitat with diverse food resources available throughout the year (USFWS 2010 p. vi). Mariana fruit bats use several forest types for foraging, roosting, and breeding, including native primary and secondary limestone forest, volcanic (or ravine) forest, old coconut plantations, and groves of *Casuarina equisetifolia* (Rice & Taisacan 1988; Worthington et al. 2001 p. 137; Wiles & Johnson 2004 p. 589,591). Most Mariana fruit bats roost during the day in maternity colonies at sites to which they show a high level of fidelity (unless disturbed). A small proportion of Mariana fruit bats, usually males, roost alone or in small groups called bachelor colonies. Within colonies, Mariana fruit bats typically group themselves into harems (one male and 2-15 females) or bachelor groups (predominantly males) (Wiles 1987a).

Population Dynamics

Population demographic information for the Mariana fruit bat is limited. Based on three-years of field observations on Guam similar to other Pteropodidae species, female Mariana fruit bats rear up to one pup annually (USFWS 2010) and likely have a gestation period of approximately 4.6 to 6.3 months (Pierson & Rainey 1992 pp. 1–17). Many *Pteropus* species typically do not give birth until 18 months of age (Pierson & Rainey 1992 pp. 1–17; McIlwee & Martin 2002 p. 76). Lifespan of substantially larger species, *P. alecto*, in Australia is four to five years, with a maximum of eight years (Vardon & Tidemann 2000).

Based on this demographic information, several authors have suggested that *Pteropus* bats have a low maximum population growth rate and thus a slow rate of recovery when a population is diminished (Pierson & Rainey 1992 p. 76; McIlwee & Martin 2002). Table 4 provides current population estimates per island and other demographic data (Mildenstein & Johnson 2017 p. 20).

Table 4. Mariana fruit bat population estimates and density by island.

Island	Forest Habitat (ha)	No. of Bats	Density
Andersen, N. Guam	25,711	45	0.00
Rota	6,663	4,149	0.62
Aguiguan	302	50	0.17
Tinian	6,481	< 25	0.00
Saipan	5,355	< 50	0.01
Farallon de Medinilla	< 1	< 5	--
Anatahan	N/A	150	--
Sarigan	169	157	0.93
Guguan	170	226	1.33
Alamagan	485	86	0.18
Pagan	1,971	1,017	0.52

Island	Forest Habitat (ha)	No. of Bats	Density
Agrihan	2,336	858	0.37
Asuncion	316	573	1.81
Maug	48	11[1]	

[1]Insufficient data available.

Status and Distribution

The Mariana fruit bat is endemic to the Mariana Archipelago. The Mariana Archipelago extends across 459 nautical miles (nmi) and is comprised of the U.S. Territory of Guam and 14 islands constituting the CNMI. The Mariana fruit bat is found on all 15 islands within the Marianas, except for Uracas, the northernmost island (Wiles et al. 1989 p. 69). The Mariana fruit bat is currently thought to be extirpated from Tinian (USFWS 2014 p. 3). A single Mariana fruit bat was photographed on Farallon de Medinilla on two occasions, in 1996 and in 2008 (DON 2013 pp. 4–123).

Mariana fruit bats in general are strong fliers and highly mobile and small groups have been observed flying over the ocean between islands (Wiles & Glass 1990 p. 2; Wiles & Johnson 2004 p. 593). Distances between are: Guam to Rota, 32.3 NM; Rota to Aguijan, 42.1 NM; Aguijan to Tinian, 4.9 NM; Tinian to Saipan, 2.7 NM; Saipan to Farallon de Medinilla, 45.9 NM; and Saipan to Anatahan, 64.3 NM. In the remaining northern Marianas, interisland distances range from 15.7 NM to 54.0 NM. All islands have a maximum elevation ranging from 551 ft to 3,166 ft with the exception of Farallon de Medinilla, which has a maximum elevation of 266 ft. All islands are visible in clear weather from the tops of adjacent islands (Wiles & Glass 1990 p. 1).

Distribution of occupied Mariana fruit bat roost sites have fluctuated sharply in the southern islands and are thought to be due to variations in survey methods, coverage, and movements of Mariana fruit bats between islands (USFWS 2010 p. 9). Initial observations of Mariana fruit bats in the southern islands (Aguiguan, Tinian, and Saipan) in 1983 and 1984 revealed populations of less than 25 to 50 Mariana fruit bats on each island. Mariana fruit bat numbers increased to about 75 to 100 individuals on Saipan in 1986 and to about 300 individuals on Aguiguan by 1988 (Wiles & Glass 1990 p. 2). Mariana fruit bats on Rota are believed to move periodically among the southern islands, and thus Rota is considered to be important to the long-term stability of the species in the southern part of the Marianas (Wiles & Glass 1990 p. 2; Wiles et al. 1995). Historic numbers of Mariana fruit bats on Guam have been between 400 and 800 since 1984, but have since been decreasing. By the early 1980s nearly all Mariana fruit bats on Guam lived in Northern Guam in a single colony, which occasionally divided into several smaller aggregations (Wiles & Glass 1990 p. 2; Mildenstein & Johnson 2017 p. 25).

Survey data in the northern islands (Anatahan, Sarigan, Guguan, Alamagan, Pagan, and Agrihan; excluding Asuncion and Maug, which were not surveyed during this time period), indicate a 40 percent decline in Mariana fruit bat numbers between 1983 and 2000 (USFWS 2010 p. 11). In the Service's 2014 5-year review, Mariana fruit bats were found to be stable or declining throughout most of their range; the only exception being on Rota where populations were increasing since 2008 due to increased enforcement of wildlife regulations (USFWS 2014).

Threats

Illegal hunting, loss of native forest, predation by the BTS on Guam, and the increased risk of extirpation or extinction faced by small, fragmented populations are the most significant threats to the survival of the Mariana fruit bat (USFWS 2014). These current known and potential threats are discussed below.

Threats:

- Loss or Degradation of Habitat:
    - Human development is a factor in habitat loss on all inhabited southern islands and on northern islands with military activity.
    - Feral ungulates and Philippine sambar deer (*Rusa marianna*) degrade habitat on many of the islands in the Marianas Archipelago. The successful eradication of feral ungulates from Sarigan and Anatahan suggests that similar projects may succeed on other islands. However, once grazing and browsing pressure is removed, the potential invasion of native forest by alien plants may be a more difficult and long-term recovery issue.
- Human Disturbance:
    - Illegal hunting is a threat to Mariana fruit bats throughout its range. Although law enforcement activity has increased since 2009 (CNMI -DLNR 2008; CNMI-DLNR 2009a, 2009b, 2010), illegal hunting of Mariana fruit bats on Rota continues and will likely resume to historical levels unless consistent, effective law enforcement efforts in tandem with education and outreach programs continue. Mariana fruit bats appear to be declining on Tinian, Saipan and Guam, and illegal hunting is thought to have greatly contributed to the decimation or decline of those populations (Wiles & Payne 1986; Wiles & Glass 1990; Sheeline 1991; Stinson et al. 1992; Esselstyn et al. 2006). As with Rota, recovery of the Mariana fruit bat on human-inhabited islands will not likely be possible without strong education programs combined with effective control of illegal hunting.
- Nonnative Snake Predation:
    - BTS prey on non-volant young left at the roost during the night, thus preventing the recruitment of young bats into the breeding population. Effective control of BTS is among the actions that must be achieved before the Mariana fruit bat population on Guam can recover. The interdiction, control, and ultimate eradication of BTS on Guam are the focus of major, ongoing projects, and the Mariana fruit bat is likely to benefit from these efforts in the long term across the archipelago. This prognosis would change drastically if the BTS were to become established widely throughout the archipelago.
- Stochastic Events:
    - Typhoons and volcanic eruptions result in mortality, reduced population viability, and habitat loss. Natural disasters can be especially damaging to the viability of smaller Mariana fruit bat populations (e.g., on Guam, Saipan, Aguiguan, and Maug). The significant loss of habitat on Anatahan after the volcanic eruption in 2003 resulted in the loss of a substantial Mariana fruit bat population that has not yet recovered.

Mariana Fruit Bat Recovery Criteria

A draft revised recovery plan for the Mariana fruit bat (USFWS 2010) addressed actions needed for the survival and recovery needs of the Mariana fruit bat. Since publication of the draft revised recovery plan, new information on the Mariana fruit bat has resulted in changes to how we look at recovery for the species. We now consider recovery in terms of stable or increasing subpopulations of sufficient size distributed across Guam and the CNMI. To meet recovery objectives, stable or increasing fruit bat subpopulations should, at a minimum, be distributed on the islands that currently have extant populations (USFWS 2010). Actions that reduce or eliminate the potential for self-sustaining populations of resident Mariana fruit bats on Guam may hamper or preclude recovery of the species. The reduction or elimination of this potential may take many forms: degradation or loss of habitat and resources required by the fruit bat for foraging, roosting, and reproduction; increased exposure of fruit bats to illegal hunting and other sources of human disturbance; and introduction of non-native predators that prey upon fruit bats. In order for the Mariana fruit bat's population to recover on Guam, sufficient amounts of functional habitat will need to be protected and restored on Guam (USFWS 2010).

Guam contains a large proportion of the remaining native limestone forest in the southern inhabited Mariana Islands, and most of that habitat is located within Department of Defense (DoD) lands. Habitat loss and degradation, illegal hunting, predation by non-native predators, and human disturbance currently impact fruit bats within the action area, outside the HMU. If threat levels increase within Mariana fruit bat habitat in the Action Area, it may further inhibit the potential for the species to recover.

Survival and Recovery Needs

Before the Mariana fruit bat is considered for delisting, the Service proposes that stable or increasing populations should exist on three of the five southern islands (Saipan, Tinian, Aguiguan, Rota, and Guam), and six of the northern islands where Mariana fruit bats have persisted historically (Anatahan, Sarigan, Guguan, Alamagan, Pagan, Agrihan, Asuncion, and Maug; (USFWS 2010 pp. 40–41). Of the six northern islands that require stable or increasing numbers, two of these must include Pagan, Anatahan, or Agrihan. Since publication of the draft revised recovery plan in 2009 (USFWS 2010), new information on the Mariana fruit bat has resulted in changes to how we look at recovery for the species. We now consider recovery in terms of stable or increasing subpopulations of sufficient size distributed across Guam and the Mariana Islands. To meet recovery objectives, stable or increasing Mariana fruit bat subpopulations should at a minimum be distributed on the islands that currently have extant populations (USFWS 2010). The final version of the Mariana fruit bat recovery plan is currently in review, and recovery criteria stated here may change upon completion of the final plan.

Of the six northern islands, the only evidence for a possibly increasing population is on Asuncion (USGS 2010 p. 33). Of the five southern islands, only Rota has achieved an increasing population. Although a conservation area containing some important habitat for Mariana fruit bats was established on Rota (USFWS 2011 p. 1), there is not currently enough protected Mariana fruit bat habitat on Rota, Guam, Tinian, or Saipan to support substantial population recovery on any of those islands. Even if sufficient habitat is set aside in conservation to support

recovery of populations, controlling illegal hunting may continue to be a challenge that limits recovery of the species (USFWS 2014 p. 5).

ENVIRONMENTAL BASELINE

Regulations implementing the Act (50 CFR 402.02) define the environmental baseline as the past and present impacts of all Federal, State, or private actions and other human activities in the action area. Also included in the environmental baseline are the anticipated impacts of all proposed federal projects in the action area that have undergone section 7 consultation, and the impacts of state and private actions which are contemporaneous with the consultation in progress.

General Environmental Baseline

A general overview of the status of, and threats to, limestone forest habitat within the Action Area, followed by species-specific environmental baseline sections, are presented below. This overview reflects the important role of forest habitat in the conservation of all the listed species addressed in this Biological Opinion.

Overview of Limestone Forest in Northern Guam

Guam is the largest and southernmost island of the Marianas Archipelago. It is almost 30 mi long and from 4.3 mi to 9.3 mi wide. The northern part of Guam is a limestone plateau interrupted by a few low hills that are volcanic in nature and other hills that are exclusively coralline (formed from coral). The original forest on limestone was of large trees, with a thick canopy overhead (see below for further description). The northern part of the island gently slopes to the southward from about 656 ft to about 328 ft at the narrow waist of the island. There is no surface water in the northern part of the island (Fosberg 1960, pp. 51-52). Only in the southern and central parts of Guam are there permanent streams (Stone 1970, p. 12). The central part of Guam includes a mixture of volcanic and limestone substrate. The southern part of Guam is hilly, largely of volcanic origin (*e.g.*, basalts) but in several places the hills are capped with a layer of limestone (Stone 1970, p. 12). The southern half of the island is made up of deeply weathered volcanic material with patches of limestone and numerous streams (Fosberg 1960, p. 52). Forest habitat is broken up by ridges and flats covered by grass. The forests in these areas tend to resemble that on limestone; however, the forest is thicker and is dominated by lower stature trees (Fosberg 1960, p. 53; Stone 1970, p. 18). At lower elevations, forest occurs primarily in ravines, valley bottoms, and on steep slopes.

Limestone Karst Forests on Guam

Limestone karsts are sedimentary rock outcroppings consisting primarily of calcium carbonate and are recognized as important ecosystems with high species diversity (Mueller-Dombois and Fosberg 1998, p. 217; Clements et al. 2006, pp. 733-734). The high species diversity on karst arises from the numerous ecological niches created by complex terrains and variable micro-climatic conditions (Clements et al. 2006, p. 734). On Guam, karst is found on an uplifted plateau located on the northern half of the island and on uplifted weathered volcanic terrain in the southern half (Fosberg 1960, p. 54; Stone 1970, p. 12; Mueller-Dombois and Fosberg 1998,

p. 241). The limestone soils of north and south Guam were historically forested (Stone 1970, p. 14; Mueller-Dombois and Fosberg 1998, p. 270; Guam Department of Agriculture 2010, p. 7), and limestone forest on Guam is composed primarily of mature growth of native trees and plants with a moderately dense canopy 33 ft to 98 ft in height (DAWR 2006, p. 19). We define primary limestone forest as forest with vegetation that was never cleared and is dominated by native species (Fosberg 1960, p. 56; DAWR 2006, p. 218).

Primary limestone forests are critically important to Guam's native flora and fauna (Stone 1970, p. 22; USFWS 2005, p. iv; DAWR 2006, p. 28; DON 2014b, p. 3-40). They retain key functional components of native forests such as large native trees and high canopy cover (Fosberg 1960, p. 56; Mueller-Dombois and Fosberg 1998, p. 217 and 270; DON 2014b, p. 3-40), and are necessary for the recovery of Guam's terrestrial native species (DAWR 2006, p. 27; Jenkins 1983, p. 22; Michael 1987; Morton et al. 1999, p. 22). Intact primary limestone forests harbor greater tree species diversity than degraded habitat (Stone 1970, p. 22) and provide habitat for a broad diversity of wildlife. These forests are also highly productive and often store more carbon than degraded forests (Caves et al. 2013, p. 7). The primary limestone forest on AAFB is considered some of the highest quality native limestone forest left on Guam to serve as habitat for listed species (Morton 1996, p. 69).

Threats to Guam's Limestone Forests

Over the past several centuries, Guam has lost much of the native forest to agriculture, a growing human population, economic development, and military activities (Mueller-Dombois and Fosberg 1998, p. 270; USFWS 2010, p. 27). The distribution of primary limestone forest on Guam has been steadily declining (Fosberg 1960, p. 54; DAWR 2006, p. 28). Although little is known about the nature of Guam's vegetation before World War II, progressive alteration of the island's vegetation clearly began with human colonization (Fosberg 1960, p. 54). On limestone soils, native forest was cleared and replaced by coconut plantations, open fields and gardens, pasture, and secondary forest (Mueller-Dombois and Fosberg 1998, p. 242). During World War II, large areas were cleared and some habitat was destroyed during heavy fighting (Fosberg 1960, p. 54).

Currently, the remaining limestone forests on Guam face numerous threats including habitat fragmentation and loss, lack of management, introduced ungulates, invasive species, typhoons, forest conversion, and loss of seed dispersers (USFWS 2005, p. 27; DAWR 2006, p. 28; USFWS 2008, p. 17-18). These combined threats are degrading the habitat quality of remaining limestone forests and limiting the acres of high quality primary limestone forest habitat available to recover listed species on Guam. Currently, forested areas cover approximately 48 percent of Guam (DAWR 2006, p. 31). Of this, about 13 percent consists of limestone forest habitat (Brown 2005 as cited in DAWR 2006, p. 28).

Forest Habitat Fragmentation, Degradation, and Loss

Habitat fragmentation is a change in habitat configuration caused by clearing, development, invasive species, typhoons, and ungulates that result in the remaining habitat to occur in patches intermixed with areas of non-habitat (Noss et al. 2006, p. 213). Habitat fragmentation creates edges that have different properties than the habitat itself. For example, edges often have

different microclimate patterns that are drier, less shaded, and warmer than forest interiors. They are often areas with increased predation and serve as entry points into native habitats for invasive vegetation, pests, and pathogens (Noss et al. 2006, p. 228). Habitat fragmentation and edges can result in localized extirpations of species, shifts in community composition, increases in invasive species, increased predation, and in suitable habitat becoming unsuitable due to pollution, invasive species, physical size, or barriers blocking access to habitats (Groom and Vynne 2006, p. 174; Noss et al. 2006, 38 pp). Habitat fragmentation has been implicated in reduced species richness, avian abundance, productivity, and food supply (Blake and Karr 1987, VanderWerf 1993, Burke and Nol 1998, Trine 1998, Porneluzi and Faaborg 1999). Overall, edges may have adverse effects to some wildlife populations and ecological processes (Murcia 1995, p. 58; Laurance 2000, p. 134) and may affect forests at larger landscape scales (Laurance 2000, p. 134).

Habitat degradation and loss on Guam has been caused by various human activities including agriculture, mining, forestry, fires, infrastructure development, military training, urbanization, industry, pollution (including light, noise, and toxic chemicals), and changes in community and ecosystem structure due to invasive species (Groom and Vynne 2006, p. 164; USFWS 2008, p. 17). Habitat loss and degradation from human activities is a threat to the recovery of many listed species on Guam (USFWS 2008, p. 17; USFWS 2012c, p. 3).

Feral Ungulates

Feral non-native ungulate species that occur on Guam include pigs (*Sus scrofa*), Philippine deer (*Rusa marianna*), and the Asiatic water buffalo (*Bubalis bubalis*). Feral ungulates have caused severe damage to Guam's forests by browsing on plants, causing erosion, inhibiting plant growth and regeneration, and facilitating the establishment of invasive plants, which can impede forest regeneration by displacing or smothering native species (USFWS 2010, p. 27). For example, deer and pigs foraging on fallen fruits and seedlings of the native breadfruit (*Artocarpus mariannensis*), an important Mariana fruit bat food, in combination with impacts from typhoons, have resulted in a decline in the number of native breadfruit trees on Guam (Wiles 2005, p. 509).

Feral pigs are extremely destructive and have both direct and indirect effects on native plant communities. While rooting in the soil in search of invertebrates and plant material, pigs directly affect native plants by disturbing and destroying vegetative cover and trampling plants and seedlings. They may also reduce or eliminate plant regeneration by damaging or eating seeds and seedlings. Pigs are a major vector for the establishment and spread of competing invasive non-native plant species, by dispersing plant seeds on their hooves and coats as well as through the spread of their feces (Matson 1990, p. 245; Siemann et al. 2009, p. 547). Feral pigs feed preferentially on the fruits of many non-native invasive plants, spreading the seeds of these species through their feces as they travel in search of food. In addition, rooting pigs contribute to erosion by clearing vegetation and creating large areas of disturbed soil, especially along hillsides (Smith 1985, pp. 190, 192, 196, 200, 204, 230–231; Stone 1985, pp. 254–255, 262–264; Medeiros et al. 1986, pp. 27–28; Scott et al. 1986, pp. 360–361; Tomich 1986, pp. 120–126; Cuddihy and Stone 1990, pp. 64–65; Aplet et al. 1991, p. 56; Gagne and Cuddihy 1999, p. 52).

On Guam, feral pigs were introduced in the 1600's, established a population by 1772, and were distributed island-wide by the early 1900's (Conry 1988, p. 26). As documented in other locations, wallowing, rooting, and trampling are common in most forested areas and can be

locally severe (Conry 1988, p. 27). A large complex of wallows and feeding sites in Tarague Basin on AAFB measured over 5.7 ac (2.3 ha), and was stripped of all ground cover with no tree regeneration (Conry 1988, p. 27). On AAFB, densities of Philippine deer and feral pigs were estimated at 0.8 deer per acre (ac) and 0.2 pigs per ac, which are some of the highest densities recorded in the world (Knutson and Vogt 2003, unpubl. manuscript).

Philippine deer were introduced to Guam in the 1770's (Safford 1905, p. 76), and are distributed throughout the island (Conry 1988, p. 27). Heavy browsing pressure has been documented and browse lines are common (Conry 1988, p. 27). Deer populations in the 1990s appeared to be expanding (Wiles et al. 1999, p. 193), and may be the largest in Micronesia (p. 200). Philippine deer have caused significant changes in forest structure and species composition in native ecosystems on Guam, and are not considered compatible with conservation of native ecosystems and recovery of endangered species (Wiles et al. 1999, p. 193).

The Asiatic water buffalo was introduced to Guam in the 1600's from the Philippines (Conry 1988, p. 27). High densities, and the gregarious habits of Asiatic water buffalo, have resulted in habitat damage such as mud wallows, broad trails, vegetation trampling, and tracks, with some areas so heavily trampled that ground cover has been denuded and soil erosion scars and slumping are evident (Conry 1988, pp. 27-28). The Asiatic water buffalo occurs primarily on the Ordnance Annex and surrounding non-Navy lands in southern Guam, with a population estimated at 50-60 animals (USFWS 2008, p. 18).

Habitat Destruction and Modification by Typhoons

Guam has been affected by typhoons in 37 of the last 50 years (USFWS 2005, p. 32). Super-typhoons (with wind gusts of over 150 mi per hour) occur approximately once every 13.5 years (the last one, Pongsona, occurred in 2002). Typhoons destroy native vegetation by opening the canopy and modifying the availability of light, and create disturbed areas conducive to invasion by non-native pest species (Asner and Goldstein 1997, p. 148; Harrington et al. 1997, pp. 539-540). Typhoons also can cause defoliation (loss of leaves), uprooting of trees, and breakage of stems, branches, and trunks of trees depending on the severity and duration of the storm and its point of impact (Brokaw and Walker 1991, p.442). Super-typhoons fragment and decrease the suitability of existing habitat, and exacerbate the effects of introduced plants and ungulates (USFWS 2005, p. 34). Climate models indicate that typhoons in the northwestern Pacific are expected to increase in intensity, frequency, and duration by 2200 (Emanuel et al. 2008, p. 360).

Climate Change

Climate change is an atmospheric response to high carbon dioxide levels caused by Federal and non-Federal actions that has significant implications on weather that will likely influence the condition of species and alter magnify the effects of human proposed actions on species. Climate change is expected to increase the number and intensity of habitat-altering typhoons and wildfire threat may increase as a result of increased frequency and intensity of drought on Guam.

Loss of Pollinators, Seed Dispersers, and Frugivores

The loss of forest birds on Guam caused by BTS predation has caused a disruption in the ecosystem services provided by birds as pollinators, seed dispersers, and frugivores (Mortenson et al. 2008, p. 2146; Caves et al. 2013, p. 7). Seeds are dispersed significantly farther from parent trees on islands with birds compared to Guam, and seed ingestion by birds doubles to quadruples the chance of germination for plant species (Rogers 2011, p. 2). The combination of loss of seed dispersal and reduced germination can produce major changes in the spatial pattern, abundance, and diversity of Guam's forests (Rogers 2011, p. 2). In addition, seed set and seedling recruitment were significantly higher on Saipan (where the BTS is absent) than Guam for bird pollinated trees (Mortensen et al. 2008, p. 2146). These studies concluded that the loss of ecosystem services provided by birds will result in the loss of species diversity, distribution, and abundance; slow regeneration of degraded forests; and a reduction of plant species recruitment (Mortensen et al. 2008, p. 2146 and 2153; Rogers 2011, p. 2; Caves et al. 2013, p. 5).

Human Disturbance

The listed species on Guam are also threatened by disturbance from human activities including, but not limited to, noise from military training (aircraft, munitions, firing ranges, vehicles, etc.), noise from recreational pursuits (hiking, and hunting), and construction noises. These disturbances not only negatively affect species, but reach into forested interiors and degrade the quality of habitat for listed species. The Mariana fruit bat is sensitive to human disturbance, and as development continues on Guam, disturbance-free forested habitats are increasingly rare on Guam.

The Service's 2017, Biological Opinion on the Department of the Navy's Relocation of U.S. Marine Corps from Okinawa to Guam and Associated Activities on Guam addressed take of all Mariana fruit bats using 2,136 ac of roosting and foraging habitat surrounding the construction and operation addressed in that consultation. Take is expected in the form of harm or harassment due to exposure to loud aircraft noise, and to noise, light, and human disturbance associated with construction and operation of the LFTRC. This includes approximately 1,817 ac in northern Guam and approximately 319 ac in southern Guam due to noise effects from military aircraft flights and training exercises. The biological impact of that taking on the fruit bat is likely to cause a significant disruption of their breeding, feeding, and sheltering behavior.

Land Management on DoD Lands

The majority of remaining limestone forests on Guam occurs on DoD lands. As noted above, the primary limestone forest on AAFB is considered some of the best native limestone forest remaining that provides habitat for threatened and endangered species (Morton 1996, p. 69). The Service and the DoD (United States Air Force (USAF), DON, and JRM) have worked together over the past 20 years to manage DoD lands for threatened and endangered species. In 1994, a Cooperative Agreement (Agreement) was established between the USAF, DON, and the Service for purposes of establishing and managing the GNWR Overlay on DoD lands (USFWS 1994). The GNWR includes approximately 376 ac (152 ha) of fee simple Service-owned land and 22,501 ac of Overlay Refuge areas on land owned by DoD. The Agreement, which is still in effect, affirms the signatory parties commitment for a "coordinated program centered on the

protection of endangered and threatened species and other native flora and fauna, maintenance of native ecosystems, and the conservation of native biological diversity in cooperation with the Guam's DAWR, consistent with the national defense mission of the Navy." Notably, all signatory parties to agreed that DON lands included within the GNWR shall be managed and administered, consistent with the national defense mission of the DON and the requirements of section 7(a)(2) of the Act, and other laws as applicable.

Management of listed species habitat on DoD lands has occurred with some success. The approximately 180 ac Haputo ERA and the 30 ac Orote Point ERA, both on NBG are two examples. Both were established in 1984, prior to the Agreement, as mitigation for the Kilo Wharf project. The 133 ac HMU was developed as a conservation measure under the 2006, informal consultation on the Beddown of Training and Support Initiative at the NWF (USFWS 2006, p. 2), and currently serves as an experimental site for BTS research and control.

Habitat Within the HMU

The once historically native-dominated limestone forest of the HMU has been replaced with degraded scrub and disturbed limestone forest with a canopy dominated by non-native *Vitex parviflora* (DAWR 2006; NAFVACPAC 2009; GPEPP 2015; NAVFACMAR 2016; Siers and Savidge 2017). The understory in the northern portion of the HMU consists of a variety of native vegetation in addition to *Vitex*; whereas, the native fern, *Nephrolepis hirsitula*, dominates the understory in the southern third of the site (Figure 5; GPEPP 2015; Siers and Savidge 2017).

The Conservation Role of the HMU

The could HMU serve a critical role in re-establishing listed vertebrates. The HMU is an interagency test site established for biological resource studies, including pilot control and monitoring programs for invasive species and forest restoration within the overlay refuge (Siers and Savidge 2017). Management and operation of the HMU were established in a partnering relationship (i.e., Adaptive Management Team) among AAFB, the Service, and the Division of Aquatic and Wildlife Resources (DAWR) within the Guam Department of Agriculture. The HMU is managed as a special use conservation area to improve Mariana fruit bat and Mariana crow habitat (USFWS 2009). Overall, the HMU management and restoration planning is occurring at the ecosystem level through the removal and exclusion of introduced species and the re-establishment and propagation of native species. A management focus is on the reintroduction of native forest bird species and management for federally-listed and other sensitive species. The HMU Restoration Plan provides guidelines for activities to assess and restore the native flora and fauna and the site is targeted for the release of native bird species no longer present on Guam due to the BTS (Siers and Savidge 2017).

Figure 5. Photo depicting typical disturbed limestone forest habitat consisting primarily of Vitex parviflora overstory and *Nephrolepis hirsutula* understory within the southern 1/3 portion of the Habitat Management Unit on Andersen Air Force Base, Guam (GPEPP 2015).

Environmental Baseline for the Mariana Fruit Bat

Other than a few isolated periods of increase, Mariana fruit bats have been declining on Guam since the early 1900s (Wiles 1987b, p. 1; USFWS 2010, pp. 6 - 7). Although the decline of the Mariana fruit bat was likely initiated by the introduction of firearms and increased hunting efficiency in the early 1900s, predation by the BTS has contributed to the continued decline (Lemke 1992, p. 137; Wiles et al. 1995, p. 32; Janeke 2006, p. 3; Brooke 2008, p. 2). By 1995, nearly all of Guam's remaining Mariana fruit bats were located on AAFB (Wiles et al. 1995, p. 39). In 2006, the only known maternity colony on Guam was located on AAFB at Pati Point and had less than 100 individuals (Janeke 2006, p. 4). By 2010 the Pati Point colony no longer existed, and no other colonies were known to exist on Guam (SWCA 2012, p. 20, DON 2014, p. 2).

From 1981 to 2008, fruit bat population estimates on AAFB were conducted by DAWR via opportunistic counts at known roosting locations (Wiles et al. 1995; Mildenstein and Johnson 2017), which, by 1994, was exclusively at Pati Point, the sole remaining maternal colony (Wiles 1994). Bat abundance at Pati Point has declined since annual surveys were undertaken

in 2005, and, by 2010, regular clustering of bats at this roosting site became unreliable (Figure 6). Consequently, from 2010 to 2013, SWCA was contracted to conduct surveys on AAFB (SWCA 2012, 2013). SWCA fruit bat surveys consisted of pre-dawn, timed (2 to 3 hour) visual surveys at 83 forested locations following methods described in the USFWS (2009) and Utzurrum et al. (2003), and direct colony counts at historical colony locations within AAFB. Surveys conducted between December of 2010 and December of 2011 produced conservative fruit bat population estimates on AAFB of approximately 25 animals (JRM et al. 2012). From March 2012 through March of 2013, a total of 50 bat detections were made in non-simultaneous counts across 84 survey locations on AAFB, although no overall fruit bat population estimate was produced for AAFB (JRM et al. 2012).

From 2014 to 2017, a collaborative fruit bat monitoring effort between University of Guam (UOG) and AAFB produced simultaneous, multi-observer (>80), base-wide counts yielding annual abundance estimates of fruit bats on AAFB (Table 5; Mildenstein et al. 2014).

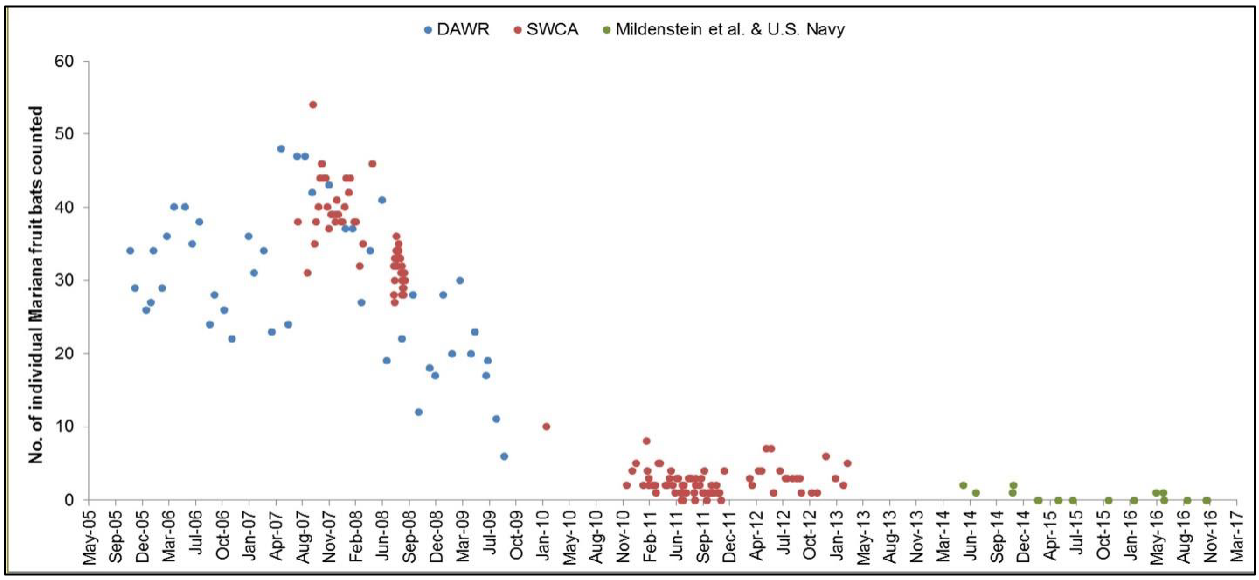

Figure 6. Mariana Fruit Bat Direct Colony Counts at the Historic Pati Point Colony Site1, Andersen Air Force Base, Guam: October 2005 to September 2009; December 2010 to December 2011; March 2012 to March 2013; and May 2014 to November 2016. Data from SWCA (2008, 2012, 2013); Mildenstein et al. (2015); DON (2017); DAWR, unpublished data. From 2017 Andersen Air Force Base Fruit Bat Management Plan (Mildenstein and Johnson 2017).

Observations of fruit bats within or near the HMU have been both incidental (e.g., as part of other fieldwork) and deliberate on surveys at designated observation stations. Therefore, methodologies by which fruit bats were documented have varied markedly in the HMU. For instance, an incidental observer documented a single fruit bat flying between Finegayan and the HMU in 2010 (USFWS 2017b). From 2011 to 2015, annual fruit bat surveys within the HMU and the surrounding area yielded annual detections of 0 to 10 fruit bats in flight, which may not have been independent observations (Table 6). From 2006 to 2017, there have been varying numbers of bats detected flying over, roosting in, or in proximity to the HMU (Table 7).

Table 5. Decadal and, when available, annual estimates of Mariana fruit bat population size on Andersen Air Force Base (and Guam when parenthetical) from the 1950s to 2016. Beginning in the 1980s, survey effort is mostly or entirely concentrated on Andersen Air Force Base, Guam. Adopted from Mildenstein and Johnson (2017).

Decade	Survey Year(s)	Estimate	Method	Source
1950s	1958	<3000* (Guam)	Roost counts	Woodside, in USFWS 2010

	2016	45	Base-wide count	DON 2016

* The methodology is not clear for this estimation.

Table 6. Maximum Mariana fruit bat sightings in or within proximity of the Habitat Management Unit (HMU) on Andersen Air Force Base in Guam for years 2010-2016. Sightings do not represent independent observations unless noted.

Year	Sightings	Method	Source
2010	1	Visual	USFWS 2017
2011	10	Station count	SWCA 2012
2012	8*	Station count	SWCA 2013
2013	2	Station count	SWCA 2013
2014	0	Station count	Mildenstein et al. 2014
2015	0	Transect count	Mildenstein et al. 2015
2016	112**	Station count	DON 2016

* Detections of individual bats in flight on or near the HMU, but only 4 likely to be unique individuals
** An estimated maximum of 112 (no more than 124) transient bats found roosting in HMU

Experimental BTS suppression was conducted at the HMU pursuant to 01EPIF00-2011-F-0211 and 01EPIF00-2011-I-0270 *Formal Consultation on the Aerial Application of Acetaminophen for Brown Tree Snake Control on Guam.* Between November 2015 and February 2016, a larger than historically-documented number of fruit bats (maximum of 112

observed) were observed within the HMU by USGS/USDA personnel conducting BTS monitoring surveys as part of a snake suppression demonstration project, and were later confirmed by AAFB natural resources personnel.

Subsequent to the observation of this influx of fruit bats into the HMU, all ground-based BTS survey efforts were suspended on 4 December 2015, and focused surveys for fruit bats were initiated in January 2016 (Lujan, 2017). Various locations in the HMU were monitored for fruit bat presence, both opportunistically and with systematic perimeter and interior forest survey methods, on 21 occasions from December 7, 2015 through August 26, 2016 (Table 7). The largest grouping of at least 112 individuals was observed on February 14, 2016 (DON 2016).

From April 7 through August 26, 2016, fruit bat numbers in the HMU declined to as few as 0 to 7 observations (DON 2016). At the time of the 2016 annual simultaneous base-wide survey (conducted on June 3, 2016), a single bat was seen from five observation stations around the HMU. Since August 2016, fruit bat aggregates have not been observed within the HMU by USDA WS fence maintenance personnel (J. Dixon personal communication November 7, 2017). Observations of fruit bat individuals in the HMU occurred daily from November 11 – 14, 2017. A pair was observed near Potts Junction on November 12, 2017 (J. Horeg personal communication December 10, 2017).

The increased occupancy of the HMU by Mariana fruit bats may have been related to the period when BTS numbers were reduced by the BTS control effort. The temporary move from Rota to Guam may also have been related to weather events such as a storm north of Guam. The HMU is not currently a known roosting site (SWCA 2012, 2013; Mildenstein et al. 2014, 2015; DON 2016).

Fecal samples (n=114) from the group of at least 112 fruit bats within the HMU in early 2016 were collected for molecular analysis to evaluate the origin of the individuals. Of the 114 fecal collections, mitochondrial DNA was successfully amplified and sequenced from 53 samples, and 42 produced microsatellite results adequate for analysis (DON 2016). From the molecular analysis, it was determined that the eruption of fruit bats found in the HMU were of the *P. mariannus mariannus* subspecies from the southern Marianas, a distinct population segment different from fruit bats from Palau or Ulithi. Results from an analysis of mitochondrial DNA weakly suggested that the fruit bats were possibly from Rota (DON 2016).

Table 7. Observations of Mariana fruit bats from opportunistic sightings (†) and surveys conducted in or near the Habitat Management Area from November 15, 2015 to August 26, 2016.

Threats to the Mariana Fruit Bat in the Action Area

In addition to the threats described in the General Environmental Baseline section, the following threats also affect Mariana fruit bat populations in North Guam.

Hunting

Humans have been using Mariana fruit bats as a food source since human arrival in the Marianas. Consumption of Mariana fruit bats represents a significant Chamorro cultural tradition (Lemke 1992, p. 135; Sheeline 1991, p. 14). Demand for Mariana fruit bats for human consumption is demonstrated by the large commercial trade in Mariana fruit bats that existed in the Marianas in the late 1960s until it became illegal through the Convention on International Trade of Endangered Species of Wild Fauna and Flora (CITES) (Wiles and Payne 1986, p. 143; Stinson et al. 1992, p. 63-66; CITES 2017). It is estimated that approximately 221,000 Mariana fruit bats were imported to Guam between 1975 and 1989 (Wiles 1992, p. 54). Illegal hunting appears to be the key reason for the Mariana fruit bat's dramatic decline on Guam (Wiles 1987b, p. 154; Wiles and Brooke 2009; USFWS 2010, p. vii).

Even though Mariana fruit bats are protected by Guam and Federal law, they are likely still hunted opportunistically on private property when they transit the island and by hunters on AAFB (GNWR, unpublished data, 2005). The number of Mariana fruit bats at the colony declined from 55 (summer 2007) to 21 (December 4, 2008 survey) (PEER 2009).

Noise

Air traffic is the primary source of noise disturbance for Mariana fruit bats on Guam (SWCA 2008, p. 2-3; SWCA 2012, p. 23, 37). The first known study examining the effects of aircraft overflights on Mariana fruit bats on AAFB was conducted at Pati Point, where a colony of approximately 400 Mariana fruit bats roosted (Morton 1996). During this study, roosting Mariana fruit bats responded to some low-altitude aircraft overflights with distress and flushing, which increased time spent in alert, aggression, and maintenance behaviors. Four-engine carriers and bombers generally elicited a greater response from roosting Mariana fruit bats than fighter aircraft. Morton (1996, p. iii) suggested that higher levels of air-traffic volume would result in increased energy expenditure and perhaps roost abandonment by some or all of the Mariana fruit bats present at AAFB.

In 2006, the effects on Mariana fruit bats from noise resulting from increased jet aircraft and helicopter use at AAFB were analyzed in the ISR-Strike BO (USFWS 2006). In that consultation, noise effects were expected to adversely affect the Mariana fruit bat to the extent that the nearby Pati Point colony would be abandoned, and Mariana fruit bats would relocate from Pati Point to other, less-protected areas on the island (USFWS 2006, p. 49). In the ISR-Strike BO, we concluded that Mariana fruit bats on Guam would be taken as a result of the proposed action, but that action would not jeopardize the continued overall existence of the Mariana fruit bat (USFWS 2006, pp. 49-52).

In 2007-2008, another study was conducted to document potential effects of aircraft noise on fruit bats at AAFB (SWCA 2008). During this period, the number of fruit bats at the Pati Point colony had decreased from 55 to 21 by the end of the surveys (PEER 2009). Aircraft noise affected the Mariana fruit bats by increasing alertness behaviors, preventing Mariana fruit bats from resting and sheltering in place, compared to surveys with no overflights occurring. However, the proportion of bats displaying alertness behaviors following an overflight was

variable. Overflights did not appear to affect active thermoregulation (a fruit bat hanging head down with at least one wing flapping). Six percent of overflights resulted in flushing events, and all flushing events were at noise levels exceeding 106 dB, the highest reading being 122.6 dB (SWCA 2008, pp. 2-3).

In 2010, another study was funded to assess the effects of aircraft noise on Mariana fruit bats at AAFB (SWCA 2012); however, the colony at Pati Point no longer existed. Although up to eight individual Mariana fruit bats were observed roosting there at any one time, most departed the site by the end of each sampling period, indicating the site was no longer used as a colonial roost (SWCA 2012, p. 2). Increases in active thermoregulation (32 percent), maintenance (14 percent), locomotion (74 percent), and alertness (62 percent) were recorded during aircraft overflights. All flush events were at recorded peak noise levels above 90 dBA/101 dBc; the highest reading at 124.9 dBA/125.5 dBc (two F-15 aircraft). The observed flush events were associated with fighter, bomber, transport, and helicopter aircraft overflights (SWCA 2012, p. 23, 37).

Typhoons

Mariana fruit bats evolved in the presence of typhoons, the principal natural disturbance in the archipelago, but today these storms are a threat to the species because they can exacerbate the effects of the anthropogenic threats listed above (USFWS 2010, p. 34). Evidence from Rota suggests that typhoons may not be a substantial source of direct mortality for Mariana fruit bats (Stinson et al. 1992, p. 65; Esselstyn et al. 2006, p. 536). However, the synergistic effect of illegal hunting and severe storms on Mariana fruit bats is documented on Rota (e.g., Stinson et al. 1992; Esselstyn et al. 2006). Severe storms can alter Mariana fruit bats foraging and roosting behavior by decimating food resources, removing protective foliage cover, temporarily modifying forest structure, and changing vegetation composition, especially by facilitating encroachment of non-native species. Loss of food resources can drive Mariana fruit bats to forage on the ground, during daylight hours, and closer to areas of human activity; thereby increasing their vulnerability to illegal hunting (Stinson et al. 1992, p. 65; Esselstyn et al. 2006, p. 532).

Mariana Fruit Bat Survival and Recovery Habitat

Although Mariana fruit bats have been observed in a variety of habitat types, they are more likely to occur in native primary or secondary limestone forest (see Status of the Species above). Mariana fruit bat populations that have been subject to intense hunting pressure (e.g., populations on Saipan, Tinian, Rota, and Guam) are sensitive to human presence, and in recent history, maternity roosts are not known to occur in close proximity to areas inhabited by humans (Wiles 1987b, p. 151; J. Boland, unpublished data 2008-2015). However, Mariana fruit bats may forage on or near human-inhabited lands, in spite of hunting pressure (Wiles 2006, pers. comm. as cited in USFWS 2006; Boland 2008-2015, pers. obs.). Therefore, for this Biological Opinion, we assume that all areas identified as limestone and ravine forests on the 2006 Forest Service landcover maps (Liu and Fisher 2006a) are potential habitat for the fruit bat on Guam. We then updated the amount of available habitat on Guam by removing all forested areas cleared since the landcover map was completed using 2011 satellite imagery of Guam (Metevier 2014, unpubl. data). Although primary limestone forest is higher quality habitat that secondary limestone forest habitat, we did not account for habitat quality in these calculations due to our inability to

differentiate between these forest categories using imagery alone. Similarly, we were unable to account for other aspects of habitat quality such as hunting and predation threats. As such, our estimate of available survival and recovery habitat (hereafter, referred to as habitat) on Guam is likely an oversetimate.

Using the methods above, the total area of Mariana fruit bat habitat on Guam was estimated to be 27,096 ac (10,965 ha). Based on our estimate of 27,096 ac (10,965 ha) of existing survival and recovery habitat for the Mariana fruit bat (Metevier 2014, unpubl. data), the estimated carrying capacity for Mariana fruit bats on Guam is 19,847 bats (DON 2013, p. 26, 45). In order for native limestone forest to serve as habitat for the Mariana fruit bat, it will need to be managed to reduce threats to the species, including the BTS, illegal hunting, invasive plant species, and feral ungulates (USFWS 2010, pp. 42-43). Only 576 ac (233 ha) of this habitat is designated for the purposes of conservation. Because much of the land set aside for conservation is not currently managed to reduce threats, protection and management of Guam's forest habitat is among the greatest conservation needs of the Mariana fruit bat.

EFFECTS OF THE ACTION

The effects of the action refers to the direct and indirect effects of an action on the species or critical habitat, together with the effects of other activities that are interrelated or interdependent with that action, that will be added to the environmental baseline (50 CFR 402.02). Indirect effects are those that are caused by the proposed action and are later in time, but still are reasonably certain to occur.

Aircraft and Human Disturbance

Aircraft noise and ground-based human activity associated with the proposed action are likely to result in harassment of all of the Mariana fruit bats at the project site. Although none of the bats observed at the HMU were accompanied by young (Mildenstein and Johnson 2017), reproductive effort and reproductive success may be reduced as a result of project-related noise and disturbance within and outside the HMU. All bats roosting or foraging within the study sites may abandon the study site and relocate to areas on Guam or on other islands where they will be exposed to BTS predation and human disturbance.

As detailed below, human activity can negatively impact bats, through disturbance from roosting and feeding sites. One or more bats may use the HMU as a roost site during project implementation. Aircraft operations will occur over the HMU roost site during 2 to 14 days for up to nine bait drop operations annually and long-term ground-based monitoring will occur up to daily on weekdays during the two month period prior to the aerial drop and for up to one year after aerial applications are completed. Operations by ground-based field personnel tracking baits following application or conducting ground operations including vegetation and fence maintenance and monitoring activities may disturb roosting bats within the project site. Low-level aircraft flights are likely to disturb roosting or transiting bats. All bats at the HMU, if present during bait drop operations, are likely to be startled and alarmed by aircraft noise. Bats exposed to high levels of noise disturbance, and to human disturbance may abandon their roost site at the HMU. They may move to other areas on Guam where habitat quality may not be as good, where BTS densities are likely to be higher, and where they are likely to be exposed to

more disturbances. The project may cause them to move to Rota or to another location where they may be exposed to high levels of hunting and decreased food and habitat availability.

Neonatal bats may be dropped by mothers when disturbed, leading to mortality. Because the HMU has not historically been known to be used by breeding bats, the risk of mortaility to juveniles due to project implementation is reduced.

Noise

Most of the bat species in the genus *Pteropus* do not echolocate, and less information is available about their hearing than for bats that do echolocate. We have no specific information on hearing for the Mariana fruit bat. The available literature indicates that fruit bats are most sensitive to noise frequencies between 10 and 20 kHz, insensitive to frequencies below one kHz, and able to detect frequencies 40 kHz or greater (DON 2014a, p. 64 and references within). From approximately four kHz to just under 20 kHz the fruit bats have more sensitive hearing than humans (DON 2014a, p. 64). Overall, fruit bat audiograms are similar to humans (DON 2014a, p. 64), and it is possible that noise from the proposed action would be heard by fruit bats as it would be heard by humans.

There is limited understanding of what sound levels may adversely affect Mariana fruit bats, and most information is from observations of fruit bat reactions to aircraft overflights. The following reactions to aircraft noise have been reported:

- Fruit bats have been reported to flush at noise levels exceeding 106 dBC (SWCA 2008, pp. 2-3) and at peak noise levels above 90 dBA/101 dBC (SWCA 2012, p. 23, 37).
- Fruit bats at a maternity colony on Rota flushed when a helicopter was within 200 m and a military jet aircraft (type unknown) flew overhead within 300 m (J. Boland, pers. obs., 2009 and 2010).
- Successive launches of F-14 repeatedly flushed 50 bats from a roost site and F-14s (95, 106 dBA) also caused agitated vocalization and flushing (Grout 1993 in Morton 1996, p. 67).
- Increases in active thermoregulation (32 percent), maintenance (14 percent), locomotion (74 percent), and alertness (62 percent) of Mariana fruit bats were recorded after aircraft overflights (SWCA 2012, p. 23, 37).

Based on this information, aircraft overflights resulting in noise over 90 dB may flush roosting Mariana fruit bats. However, flush rates may not adequately reflect a species' sensitivity to human disturbance. Effects to individual Mariana fruit bats are only documented in the SWCA (2012) study, which occurred after the Pati Point colony site was no longer used; however, this study did not report noise levels of overflights that may have disturbed (other than flushing) individual fruit bats. Therefore, we do not have direct data on how an individual fruit bat on Guam will react to noise disturbance from the proposed action. For the purposes of this consultation, we will assume that, at a minimum, noise over 90 dB may flush a roosting Mariana fruit bat.

Ambient noise levels in the HMU have not been studied, but the site is within 3.3 mi of the runways at AAFB and the most often used aircraft landing approach to the runways is within 1.6 mi. of the HMU. The HMU is also exposed to vehicle noise from Route 3A. Data is available for

the average daily noise level (ADNL) measured at three sampling sites near the proposed live-fire training range complex in Northwest Field (NWF LFTRC) 3 mi from the HMU. In this study, ambient noise was not recorded to be less than 50 dB and was often above 65 dB (DON 2014b; DON 2015).

Regardless of the size or type of aircraft used in implementation of the proposed action, the aircraft is likely to cause sound levels to exceed 90 dBA in areas occupied by roosting and foraging bats. A small Bell 206/MD900 noise level is 94 dBA (at 100 ft distance, in A-weighted decibels) (Falzarano and Levy, 2007). The MD-600 helicopter is likely to produce a sound level of 72.7 dBA during an overflight at 123 m (400 ft) altitude (Falzarano and Levy 2007), which would correspond to a sound level of approximately 79.7 dBA at 200 ft and 86.7 dBA at 100 ft (assuming 7 dB sound reduction per doubling of distance from noise source), within the proposed 82- to 246- ft offset distances of the proposed helicopter flights.

Noise levels above ambient levels and below 90 dB are likely to cause other stress reactions, including increases in active thermoregulation, maintenance, locomotion, and alertness. Stress reactions caused by human disturbance can have an adverse effect on fruit bats by increasing energetic demands, disrupting hormonal balance, and forcing relocation to lower quality habitat (Klose et al. 2006, p. 347, and references therein; CNMI 2010, p. 7). All of these factors can lead to reduced time foraging, sheltering, or breeding and adversely affect survival. When a disturbance is experienced by a Mariana fruit bat colony, individuals may disperse on their own or in smaller groups (CNMI 2010, p.6). In some cases, the degree of colony dispersal (i.e., how many individuals leave the main colony) may be related to the degree and/or type of human disturbance. For example, if hunters are frequently targeting bats along commuter flyways near the colony roost site, some individuals may disperse away from the roost site temporarily, but eventually return. However, if hunters fire directly into a colony at their day roost, the entire colony abandons the site (CNMI 2010, p. 7). When fruit bats on Rota are forced to disperse from colonies as a result of human disturbance, infant mortality may increase because dependent, non-volant pups that are too big for the mother to carry are likely abandoned. Forced dispersal may negatively affect the reproductive potential of the population because access to mates is compromised (CNMI 2010, p. 7). Even without dispersal, high levels of stress from any disturbance can disrupt reproductive cycles and/or lead to miscarriage (Wingfield et al. 1998, p. 192-193, Heideman 2000, p. 169-199, Klose et al. 2006, p. 347).

Other Human Disturbance

Transect maintenance and ground-based monitoring activities will result in an increase in noise and other human disturbance at the study sites. In many parts of their range, bats are exposed to poaching, so bats may be sensitive to the scent of humans conducting ground operations below their roost sites. Solitary bats flushed as a result of project disturbance may travel to another area where the likelihood of harassment and snake predation are greater overall than it is at the HMU. Human activity can also impact fruit bats thus increasing energetic demands (Wiles et al. 1995; SWCA 2012). BTS ground monitoring crews would be in the HMU weekly for up to two months prior to the first bait applications, and then again weekly or monthly for up to one year following the last bait drop.
